HIGHLIGHTS

- Microbial-based biofuel as a promising waste-to-energy technology has been scrutinized.
- Microbial production of bio-jet fuel is possible through DSHC, AtJ, and GtL.
- Future application of ammonia as bio-fuel requires special design of ICE.
- Cons and pros of microbial liquid fuels over gasoline have been outlined.
- Conversion of microbial liquid fuel into fuel derivatives has been discussed.

Fuel additive

ABSTRACT

Environmental deterioration, global climate change, and consequent increases in pollution-related health problems among populations have been attributed to growing consumption of fossil fuels in particular by the transportation sector. Hence, replacing these energy carriers, also known as major contributors of greenhouse gas emissions, with biofuels have been regarded as a solution to mitigate the above-mentioned challenges. On the other hand, efforts have been put into limiting the utilization of edible feedstocks for biofuels production, *i.e.*, first generation biofuels, by promoting higher generations of these eco-friendly alternatives. In light of that, the present review is aimed at comprehensively assessing the role and importance of microorganisms such as bacteria and yeasts as catalysts for sustainable production of liquid biofuels including bioethanol, biomethanol, biobutanol, bio-ammonia, biokerosene, and bioglycerol. Various aspects of these biofuels, *i.e.*, background, chemical synthesis, microbial production (including exploitation of wild and metabolically-engineered species), and product recovery as well as the derivatives produced from these biofuels which are used as fuel additives are thoroughly covered and critically discussed. Furthermore, the industrial features of these green liquid fuels including the industrial practices reported in the literature and the challenges faced as well as possible approaches to enhance these practices are presented.

1. Introduction

Mortality from air pollution is greater than that from AIDS/HIV, tuberculosis, and road accidents combined. Indeed, as many as 6.5 million deaths occur annually worldwide from air pollution related illnesses, of which 3 million deaths are attributable to outdoor pollution, and number of deaths due to this pollution is expected to be 4.5 million by 2040 (Lancet, 2016; Kazemi Shariat Panahi et al., 2019a). For example, an estimated 50,000 people die annually from air pollution related diseases in Britain (Vidal, 2015). A recent estimate released by experts of the World Bank indicates that premature deaths associated with air pollution, fine particulate matter (PM) and ozone (O₃), account for US\$ 225 billion and US\$ 5.11 trillion in loss of income and reduced personnel welfare, respectively, thus, reducing productivity in the workforce (World Bank, 2016; Kazemi Shariat Panahi et al., 2019a). These losses are greater than the gross domestic products of many industrialized countries, including Canada and India (World Bank and Institute for Health Metrics and Evaluation, 2016). The cost of losses due to compromised environmental quality could be greater if a wider range of pollutants and associated effects on health were considered (Amini and Sowlat, 2014).

Emissions from industrial facilities, power plants, and transportation vehicles are major source of outdoor pollution. Because air pollution cannot be constrained by borders, implementation of effective mitigation strategies requires coordinated efforts across organizations and nations (Kazemi Shariat Panahi et al., 2019a). For example, scientists and politicians of different nationalities urged the leadership of all countries to have a unified approach in addressing global air pollution problems and detrimental effects for animal and plant habitation on the earth during the Paris climate summit (Kazemi Shariat Panahi et al., 2019a). Although emissions can be reduced through the use of post-combustion control techniques, the generation of forms of energy that do not result in high levels of pollution provides for a more sustainable and effective solution to pollution problems (Aghbashlo et al., 2018; Rahimzadeh et al., 2018).

On the other hand, population growth and lifestyle changes result in greater pollution with development and growth of cities and the resulting energy use in concentrated physical locations. For example, 85% of air pollution generated in 2013 in Tehran, Iran, a city of 8.2-million residents, came from transportation vehicles, whereas emissions from industries, energy conversion, households, and terminals accounted for the remaining portion (Shahbazi et al., 2016). The pollutants include carbon monoxide (CO), nitrogen oxides (NO_x), PM, sulfur oxides (SO_x), methane (CH₄), and volatile organic compounds (VOCs). The mobile nature of air pollutants poses even greater risks to people in developing countries than those living in the developed world, given the high mortality rate in these countries typically caused by poverty as well as poor infrastructure and medical care. In addition to health problems, these pollutants contribute to a global warming effect (Kazemi Shariat Panahi et al., 2019c). Indeed, pollution due to transportation resulted in generation of 7.0 GtCO₂eq of direct greenhouse gas (GHG) emissions (non-CO₂ gases included) in 2010, hence is responsible for approximately 23% of total energy-related CO₂ emissions (United Nations, 2015). Accordingly, the calculated values for GHGs emissions over a 40-year period indicate a 2.5-fold increase from 1970 to 2010, with the emission from the road transportation sector accounting for almost three quarters of these emissions.

While electricity generation from natural resources such as solar, wave, and wind (which will result in less air pollution) has the potential to replace the energy from coal-burning power plants, the technology for retrofitting the physical infrastructure of the transportation sector to use such renewable energy carriers has not been developed yet, is inefficient, and/or expensive. Consequently, the current number of 1.2 billion vehicles on roads worldwide continue to result in a huge reliance on fossil fuels for operation if cogent progress is not made in the area of alternative non-fossil based production of fuels (Kazemi Shariat Panahi et al., 2019c). On the other hand, there are estimates that the total number of road vehicles worldwide will increase to 2 billion by 2035 (Voelcker, 2015). If the environmental and health effects of air pollution as a result of GHGs emission are not addressed through a cohesive strategic plan which includes gradual replacement of fossil-fuels with liquid biofuels (such as butanol, ethanol, methanol, biokerosene, etc.), the detrimental effects of fossil-based fuels emissions will continue to contribute to environmental demise. In addition to pollution concerns, energy sources such as crude oil and gas that are the main feedstock for the production of different fuels and chemicals are not renewable. This concern has been expressed by

scientists, as well as leaders of many countries, who have long-term energy strategic plans.

Microorganisms are potent producers of various value-added bio-products through assimilation of cheap residues and wastes (Hamed et al., 2015b; Mohammadipanah et al., 2015). At present, the application of microbial-based technologies has significantly contributed to solving various problems encountered by humans, ranging from antibiotic and enzyme production to bioremediation and even disease prevention (Hamed et al., 2015a; Mohammadipanah et al., 2016; Panahi et al., 2016; Dehghani and Mohammadipanah, 2017; Dehghani et al., 2018a and b; Sajedi et al., 2018; Dehghani et al., 2019). In line with this, the present review comprehensively presents and discusses chemicals with promising liquid fuel properties produced using fermentation of biomass by bacteria and yeasts. The focus is on production, fuel properties, and derivatization of chemicals with biotechnological significance. Factors are also identified that impede commercial fermentative production of chemicals, and approaches are recommended to address feasibility challenges for bio-production of these compounds. For reference purposes, gasoline properties (Table 1) will serve as the standard for comparing biofuels that are addressed in this review.

Table 1.
Fuel properties of gasoline.

Chemical formula	Hydrocarbons with 4 to 12 carbon atoms
Boiling point (°C)	100 - 400
Composition, weight % C	85-88
Density (kg/m ³)	719-760
Ignition temperature (°C)	247-280
Thermal expansion coefficient (K ⁻¹)	900×10 ⁻⁶
Viscosity (m ² /s)	0.5×10 ⁻⁶
Flammability limits, vol %, lower, higher	1.4, 7.6
Air-fuel ratio (kg/kg)	14.7
Heat of vaporization (MJ/kg)	0.36
Calorific value (MJ/kg)	46.7
Research octane No.	90-98
Motor octane No.	85-87
Cetane No.	5-20

2. Methanol

2.1. Development of methanol as fuel: attributes, challenges and mitigating strategies

The use of alcohols (*i.e.*, methanol or ethanol) as fuel has been considered an option since the time of development of the internal combustion engine (ICE) because some of the engines were designed to operate with alcohol as fuel with the aim of upgrading steam engines as the technology of engine design improved (Olah et al., 2011). Methanol has been the fuel of choice for Indianapolis-type racecars (Indianapolis, Indiana State, USA) since the 1960s due to its superior performance as well as safety attributes (Table 2). Methanol, however, lost favor as a major fuel mainly due to discovery of petroleum deposits from which energy could be derived that was more economical. Interest in the use of alcohols as fuel was rekindled during the 1973 oil crisis when the Organization of Arab Petroleum Exporting Countries (OAPEC) sanctioned some western countries for the support of Israel, which resulted in an increase in cost of petroleum-derived products. Consequently, a study was conducted in 1973 through which an engine was developed with very desirable gas mileages and relatively lesser pollution when a methanol-gasoline blend was used as an energy source (Reed and Lerner, 1973). Soon after, in 1975, Volkswagen conducted a field test with 45 vehicles where engines were slightly modified to operate with use of a 15% blend of methanol-gasoline (Hal et al., 1982). Interestingly, the use of methanol as an energy source resulted in a greater octane rating of the engine fuel and there was a greater

Table 2.
Fuel properties of methanol.

Chemical formula	CH ₃ OH
Structure
Molar mass (g/mol)	32.04
Boiling point (°C)	64.7
Melting point (°C)	-97.6
Composition, weight %C	37.5
Density (kg/m ³)	792
Ignition temperature (°C)	470
Flash point (°C)	11-12
Thermal expansion coefficient (K ⁻¹)	0.00149
Viscosity (m ² /s)	7.37×10^{-7} at 20°C
Flammability limits, vol.%, lower, higher	7.3, 36
Calorific value (MJ/kg)	22.7
Air-fuel ratio (kg/kg)	6.4
Vapor pressure	32 kPa
Heat of vaporization (MJ/kg)	1.2
Research octane No.	108.7
Motor octane No.	88.6
Cetane No.	5

amount of engine power than with use of pure gasoline. Similarly, 84 vehicles were operated with pure methanol as fuel in a partnership involving Ford and Volkswagen Motor companies, and the engines of the vehicles had a greater efficiency and durability than the engines of gasoline-powered vehicles (Perry and Perry, 1990). There were efforts by the California State Government in promotion of M85 fuel, which is a blend consisting of 85% methanol and 15% gasoline (Olah et al., 2011), that resulted in the production of approximately 20,000 units of FFVs by 1997 (Energy Information Administration, 1988) which indicates the desirable fuel properties of methanol. The introduction of FFVs with the capacity to operate when any blend of alcohol with gasoline or alcohol alone was used, indicates that methanol is a credible liquid fuel (Olah et al., 2011).

Use of methanol as transportation liquid fuel has some challenges and shortfalls. Indeed, methanol has different physicochemical characteristics such as a relatively greater dipole moment and dielectric constant, and being miscible with water compared to gasoline. Furthermore, when methanol concentration exceeds 10% in gasoline-methanol blends, the fuel may be incompatible with some of the engine components such as the distributor, connector, as well as fuel storage and delivery system in gasoline-powered automobiles. Another shortfall with use of methanol is the corrosion of some metals such as aluminum (Al), magnesium (Mg), and zinc (Zn) components of automobiles (Bechtold, 1997) while the problematic reaction of methanol with some plastics, gaskets, rubbers, engine oil and greases must also be considered before use to avoid leaks or system malfunctions (Olah et al., 2011). To mitigate these limitations, methanol-resistant compounds such as steel and cast iron must be used for building components of systems that have direct contact with methanol. These modifications are assumed to be only a marginal limitation from use of methanol as these alterations do not significantly increase the overall production cost of the system (Olah et al., 2011). Meanwhile, there is "cold-start" problem associated with use of pure methanol as an energy source for engines. This problem can be mitigated with either addition of small amounts of highly volatile compounds (e.g., butane [C₄H₁₀], isobutene [C₄H₈], or pentane [C₅H₁₂]) (Cheng and Kung, 1994) or installation of a device that can atomize or vaporize methanol into easily-ignited minute droplets (Olah et al., 2011). It should be noted that "cold-start" problems have

not been observed when M85 fuel is used in FFVs even in the coldest climates (Olah et al., 2011).

Interestingly, a tri-flex-fuel car (Exige 270E) with the capacity for use of mixtures of ethanol, gasoline and methanol was unveiled in 2006 by the Lotus Car Company (News Release Lotus Engineering, 2008). The company emphasized on the fuel properties of methanol and its suitability for ICEs in terms of performance, thermal efficiencies, and pressure-charging (News Release Lotus Engineering, 2008) as corroborated with combustion properties presented in Table 2. Compared to gasoline (Table 1), methanol has a greater research octane rating of about 109; allowing less compression of the air-to-fuel mixture before ignition by the sparkplug. The latent heat of vaporization of methanol allows the removal of generated heat from engines through possible application of air-cooled radiators instead of water-cooled systems. There are some highly positive attributes of optimized methanol-powered engines such as greater acceleration and mileage with use of smaller and lighter engine blocks that require lesser cooling, as compared to gasoline engines, while at the same time there is less overall air pollutant emissions such as hydrocarbons (HCs), particulates, NO_x, and sulfur dioxide (SO₂) (Nowell, 1994; Olah et al., 2011). These advantages compensate for the lesser energy density of methanol, which is about half of that of gasoline (Olah et al., 2011).

Methanol can be dehydrated to dimethyl ether (DME), which was first introduced as a diesel fuel during the 1990s. Methanol is commonly used for transesterification of oils and fats derived from vegetable matter, animal tissues, and microorganisms (Tabatabaei et al., 2019a) (see Section 7), and it is an excellent carrier for hydrogen (H₂) fuel as each liter of methanol at ambient temperatures contains approximately 99 g of H₂, compared to 71 g with liquid H₂ at -253 °C (Olah et al., 2011). The absence of C-C bonds, which are not easily broken, significantly facilitates *in situ* steam transformation of methanol at 250 to 350 °C to high purity (80-90% efficiency) H₂, with no NO_x generation (Romm, 2004; Olah et al., 2011). In addition to transportation and other mobile applications, methanol can be used for static applications such as electricity and heat generation. In this regard, using methanol as an energy source can occur in gas turbines of transport vehicles more efficiently than natural gas or light petroleum distillate fractions while there is less generation of NO_x and zero SO₂ emissions (Temchin, 2003; Olah et al., 2011). It is also easier to use and safer to transport than natural gas.

When there is a fire and/or explosion, methanol gas concentration in air must be four times greater than that of gasoline for ignition to occur, whereas its rapidity of burning is almost four times less while there is a release of one-eighth the heat, compared to gasoline (Olah et al., 2011). The methanol has a lesser radiant heat output and, therefore, a fire is less likely to spread to nearby flammable materials than is the situation with gasoline fuel. The relative risk of flammability with use of gasoline- and methanol-powered cars was tested and it was revealed that with gasoline-powered cars, ignition of the fuel was more rapid and entirely within minutes when the leaked fuel was subjected to an open flame. In contrast, with methanol there was no flammability for a three-fold longer time and the fire was restricted to only the rear of the car (Cheng and Kung, 1994). Based on this study, the Environmental Protection Agency concluded that substitution of gasoline with methanol would decrease the fuel-related fire incidents by 90%. Additionally, methanol burns more cleanly, reducing the risks of smoke inhalation associated injuries, and more clearly, resulting in a light blue flame that is visible in most situations and is easily distinguishable.

2.2. Chemical synthesis of methanol

While there are various potential techniques to produce methanol, almost all methanol that is currently marketed is exclusively produced from carbon oxides (CO and CO₂) and H₂ in an ideal stoichiometry composition value (S) of about two (Eq. 1) through use of a syngas production process. These gases, known as syngas or synthesis gas, are derived from CH₄ sourced through natural gas, coal, petroleum resources, and biogas. These processes may be conducted at different temperatures and pressures such as: (i) 800 to 1000 °C, 2 or 3 MPa with a nickel (Ni) based catalyst addition for steam reforming; (ii) 800 to 1500 °C, 0.5 to 4 MPa with/without a catalyst for partial oxidation (POX); and (iii) a process developed by Johnson Matthey (formerly ICI Syntex) which operates at 200 to 300 °C, 5 to 10 MPa with addition of a copper-zinc oxide- (Cu-ZnO) based catalyst (Kochloeff, 1997;

Fiedler et al., 2003; Choudhary and Choudhary, 2008). Using these processes, a 99.8% methanol selectivity and energy efficiency as high as 75% may be obtained (Olah et al., 2011). Currently, the most commonly used feedstock for the production of methanol is natural gas, for example, mega-methanol plants in Iran produce methanol at USD100/t. It should be noted that transformation of other feedstocks such as coal, petroleum oil, and long-chain HCs to methanol is relatively expensive as generation and purification costs to remove impurities such as sulfur that destroys catalyst systems from the intermediate product, i.e., syngas, increase the cost of production. Indeed, syngas generation generally accounts for as much as 70% to 80% of the total investment for syngas-based methanol-producing plants, depending on the type of feedstock (Hansen, 1997).

$$S = \frac{(\text{moles H}_2 - \text{moles CO}_2)}{(\text{moles CO} + \text{moles CO}_2)} \quad \text{Eq. (1)}$$

2.3. Biological production of methanol: significance of CH₄ in methanol-producing microorganisms

Two groups of bacteria, methanotrophic and ammonia-oxidizing bacteria (AOB), can convert CH₄ to methanol in aerobic conditions (Hanson and Hanson, 1996; Taher and Chandran, 2013). Methanotrophic bacteria can function to activate and oxidize the stable C-H bond of CH₄ as a result of the action of the CH₄ monooxygenase (MMO) enzyme, thus, facilitating the use of CH₄ as a carbon (C) source. In the AOB, there can be use of ammonia (NH₃) as the nitrogen (N) source in a process that results in partial oxidation of CH₄ to methanol. Additionally, some methanotrophic bacteria and archaea have the capacity to produce methanol through anaerobic oxidation of CH₄ coupled with the reduction of nitrite (NO₂⁻) and sulfate ions (SO₄²⁻), as well as manganese (Mn), or iron (Fe) in the growth medium (Boetius et al., 2000; Beal et al., 2009; Ettwig et al., 2010; Ge et al., 2014). Notably, no anaerobic methanotrophs have been isolated either in a consortium or in a pure culture (Haynes and Gonzalez, 2014). Aerobic methanotrophic bacteria are classified in two classes of *Proteobacteria*, i.e., α -*Proteobacteria* and γ -*Proteobacteria*. These two classes of *Proteobacteria* comprise 16 genera that include *Clonothrix*, *Crenothrix*, *Methylobacter*, *Methylocaldum*, *Methylocapsa*, *Methylocella*, *Methylococcus*, *Methylohalobius*, *Methylosoma*, *Methylosphaera*, *Methylosarcina*, *Methylosinus*, *Methylosoma*, *Methylosphaera*, and *Methylothermus* (Semrau et al., 2010; Ge et al., 2014). Methanotrophs can also be categorized into two groups, i.e., facultative and obligate. For facultative methanotrophs, the primary C or energy source is generally C1 substrates of which CH₄ is the most common substrate type, whereas obligate methanotrophs assimilate C1 as well as multi-C substrates (Theisen and Murrell, 2005). For example, *Methylocapsa aurea*, *Methylocella* sp., and *Methylocystis* sp. are facultative methanotrophs (Dedysh et al., 2005; Dunfield et al., 2010). It should be noted that the most precisely characterized methanotrophic strains are obligate methanotrophs with the exception of *Methylocella silvestris* BL2, which is a facultative methanotroph (Ge et al., 2014). The identified AOB are classified into five genera of *Nitrosomonas*, *Nitrosococcus*, *Nitrosolobus*, *Nitrospira*, and *Nitrosovibrio*. All these genera belong to the class β -*Proteobacteria*, except *Nitrosococcus* that are of the γ -*Proteobacteria* class. These bacteria co-oxidize CH₄ and NH₃ with catalytic action of NH₃ monooxygenase (AMO) during a two-step process that oxidizes NH₃ to NO₂⁻ or to hydroxylamine (NH₂OH); subsequently, hydroxylamine is oxidized to NO₂⁻ by NH₂OH oxidoreductase. Compared to methanotrophs, the efficiency of bio-conversion of CH₄ to methanol by AOB is less. Furthermore, a major disadvantage of AOB is the capacity to produce nitrous oxide (N₂O), one of the four main GHGs with the greatest contamination capacity as it has more than 300 times the GHG effect of CO₂ (Stein and Yung, 2003).

The CH₄ compound is the major component of natural gas (up to 98%) with 194 trillion m³ of global reserves reported to exist in 2012 (Ge et al., 2014). Microbial conversion of CH₄ to methanol is an environmentally compatible processing option for conversion of gas into liquid fuel. Additionally, CH₄ constitutes the major component of biogas (60%-70%, v/v) produced using anaerobic digestion of organic wastes (Jingura and Kamusoko, 2017; Shirzad et al., 2019; Tabatabaei et al., 2019b). Although CH₄ is a high quality fuel source, it is difficult to store and transport, and there is often requirements for considerable energy inputs and large capital expenditures for its transport to the final consumer. Furthermore, emission of CH₄ to the atmosphere is hazardous as it is believed to account for 17% of the global warming effect of emissions (Stocker et al., 2013). To address these issues, CH₄ can be efficiently converted

into a fuel (such as methanol) that is environmentally compatible with use of chemical and microbial processes. Use of biogas (i.e., CH₄), instead of natural gas, as a feedstock for biological production of methanol is receiving considerable attention because the process allows the conversion of decomposing organic wastes into valuable products and facilitates the attainment of long-term energy sustainability (Ge et al., 2014). Furthermore, the biological CH₄ to methanol conversion process can be implemented for use of impure CH₄ as a feedstock, unlike the chemical process where pure CH₄ is required without having impurities such as hydrogen sulfide (H₂S), NH₃, and siloxane. With the chemical process, there needs to be economically costly inactivation of these impurities through use of metal catalysts that facilitate the use of this conversion process.

For example, biogas may contain as much as 1000 ppm H₂S depending on the abundance of SO₄²⁻-reducing bacteria that reduce SO₄²⁻ to H₂S in the anaerobic digester. Notably, H₂S and NH₃ can inhibit the growth of methanotrophs (such as *Methylosinus trichosporium* OB3b) if concentration of these compounds in the bioreactor exceed optimal threshold (typically 0.13 and 0.05%, respectively) (Ge et al., 2014). Some pure and mixed cultures of methanotrophic bacteria are capable of metabolizing crude biogas. Indeed in the presence of crude biogas, there is an increase in density and optimal growth rate in cultures of *Methylocystis parvus* OBBP, *Methylocaldum* sp. 14B, and *Methylocaldum gracile* SAD2; and two methanotrophic consortia, (i) a consortium of *Methylosinus sporium* NCIMB 11126, *M. trichosporium* OB3b and *Methylococcus capsulatus*, and (ii) a thermotolerant methanotrophic consortium otherwise known as MC-AD3 (Criddle et al., 2012; Han et al., 2013; Sheets et al., 2016; Zhang et al., 2016; Su et al., 2017). The capacity of these bacteria to metabolize CH₄ in crude biogas is noteworthy because the cost of H₂S removal from biogas may be as high as USD 0.38/m³ CH₄. Some aerobic methanotrophs can oxidize H₂S in biogas when these microbes are exposed to small amounts of air in an anaerobic digestion system (Ge et al., 2014). The biogas can also be purified using NH₃ stripping processes to separate NH₃ (Walker et al., 2011). Nevertheless, H₂S- and/or NH₃-tolerant methanotrophs such as *M. gracile* SAD2, *Methylococcus albus*, and *Methylocystis* sp. have also been isolated (Cáceres et al., 2014; Zhang et al., 2016).

Overall, *M. trichosporium* is the most studied of the methanotrophic microbes for methanol biosynthesis. *M. trichosporium* has high specific activities of soluble methane monooxygenase of 85 nmol/min/mg protein [reductant, 5 mM reduced nicotinamide adenine dinucleotide (NADH); substrate, CH₄; and absence of Cu] and 93.5 nmol/min/mg protein [(reductant, 1 mM duroquinol; substrate, propylene (C₃H₆)], and particulate methane monooxygenase (pMMO) activity of 13.3 mol/mol Cu/protein] (Colby et al., 1977; Chan et al., 2011). Notably, the presence of Cu²⁺ (10 μ M) improves specific growth rate of *M. trichosporium* OB3b (Park et al., 1992), and the use of paraffin oil (5% v/v) as substrate results in a greater growth rate and cell density of methanotrophs because it increases mass transfer of CH₄ between the gas and aqueous phases (Han et al., 2009). Beyond pure cultures of methanotrophs, mixed cultures have also been studied (Han et al., 2013). Two of the most important mixed cultures ever studied are a three-bacterial-association of *M. sporium* NCIMB 11126, *M. trichosporium* OB3b, and *M. capsulatus*, and the thermotolerant methanotrophic consortium, i.e., MC-AD3 (Han et al., 2013; Su et al., 2017).

Because MMO is a very important enzyme for function of these microorganisms in the catalysis of CH₄ to methanol, cloning and expression of the gene for this enzyme in *Escherichia coli* and the subsequent use of the generated recombinant *E. coli* or enzyme in methanol biosynthesis seems to be an attractive opportunity. The cofactor requirements for MMO catalysis and problems associated with MMO instability, however, make the utilization of pure MMO difficult, an impediment that does not exist when methanotrophs (i.e., whole cells) are used. Nonetheless, methanotrophs often oxidize methanol to CO₂ through transfer of an electron from methanol to cytochrome C_L (Anthony, 1992). Methanol dehydrogenase (MDH), a pyrroloquinoline-containing enzyme, is the enzyme responsible for the catalytic oxidation of methanol to CO₂. By distorting the active site of MDH and adding formate to the medium to serve as an electron donor for maintenance of cell viability (Ge et al., 2014), oxidation of methanol to CO₂ may be prevented and thus, facilitating the accumulation of methanol in the bioreactor. However, one of the main

constraints on the way of commercial exploitation of this approach is that application of formate for this purpose renders the industrial production of methanol not economically feasible. Therefore, there is the need to develop alternative approaches that are less economically costly to meet the electron donor requirement for methanol production (Ge et al., 2014). On this basis, the use of facultative aerobic methanotrophs for the production of methanol have been suggested because these microbes have the capacity to utilize mono- or multi-C compounds such as acetate and other volatile fatty acids as the energy source for growth and methanol production (Dedysh and Dunfield, 2011). Alternatively, electrotrophic methanotrophs, which have the capacity to accept electrons from electrodes, could be investigated as useful microbes for methanol production. Indeed, formate could be produced through electrochemical CO₂ reduction coupled with H₂O oxidation utilizing tungsten-containing formate dehydrogenase (Reda et al., 2008). The generation of formate by microbial electrosynthesis is an economically viable prospect for formate production (Ge et al., 2014).

Likewise, supplementation of the growth medium with ethylenediaminetetraacetic acid or ethylene glycol tetraacetic acid (EGTA) is a plausible strategy for chelating the Ca²⁺ in the MDH structure and detouring its active site. In fact, the conformation of the active site of MDH is maintained by Ca²⁺ (Zheng and Bruce, 1997). Interestingly, relatively greater titers of monovalent cations (50-200 mM) such as dipotassium hydrogen phosphate (K₂PO₄), potassium sulfate (K₂SO₄), and sodium chloride (NaCl) have been reported to be potent reducers of the activity of MDH and obstruction of methanol oxidation (Cox et al., 1992). Additionally, cyclopropanol in amounts as small as 3 μM (Takeguchi et al., 1997) inhibit the activity of MDH by as much as 50% through interaction with pyrroloquinoline quinone (free or bound). Cyclopropanol undergoes an irreversible reaction with MDH to form a stable C5 3-propanal adduct of pyrroloquinoline quinone (Frank et al., 1989). The greatest disadvantage of using cyclopropanol for the inhibition of MDH, however, is the susceptibility of the compound to oxygen- (O₂) and instability in aerobic conditions (Han et al., 2013). Nevertheless, significant progress on microbial conversion of biogas to methanol is needed to produce methanol at titers that justify industrial scale production. There has been no commercial microbial-based methanol plants constructed or operational because of the impediments described above, thus, emphasizing the need for an enhanced research focus on these realms.

2.4. Methanol derivatives as fuel components: production, application, and performance

Methanol is a feedstock alcohol that can easily be converted into other fuels and fuel additives (Fig. 1). Direct conversion of methanol into ethanol can occur using a two-step process. The first step involves reductive carbonylation of methanol to acetaldehyde in the presence of rhodium- (Rh) based catalysts. In the second step, acetaldehyde is reduced to ethanol with the incorporation of ruthenium (Ru) as a co-catalyst.

Some commercial gasoline detergents that improve vehicle fuel economy by functioning as cleaning agents of intake valves, can also be produced using methanol as the major feedstock (Fig. 1). For example, the styrene oxide which is used in polyisobutylene-phenolic-styrene oxide ammonium acetate (PIBP-SOAA) production can be prepared by reacting methanol-derived formaldehyde with toluene to form styrene in separate reactors followed by epoxidation of styrene with peroxybenzoic acid in the Prilezhaev reaction (Butler and Pelati, 2010; DeRosa, 2012). The DME compound can be derived by dehydration of methanol utilizing a mildly acidic catalyst with no need for isobutylene inclusion. The DME compound is an eco-friendly chemical, non-corrosive, non-carcinogenic, and non-toxic, which is superior and contains greater amounts of calorific fuel than methanol, and can be used to operate diesel engines. Similar to liquefied petroleum gas (LPG), DME is generally stored in liquid state in pressurized tanks. The exhaust gas from DME burning contains no black smoke, soot, or SO₂ and there is only the release of very small amounts of NO_x and other emissions (Olah et al., 2011). Additionally, DME can be used as a fuel additive for gasoline or diesel fuel.

Methyl *tert*-butyl ethers (MTBE) have been produced at a commercial scale since the 1970s for fuel industry application. In the 1980s, MTBE was increasingly utilized as an octane booster and an "antiknock" additive for gasoline following the phasing out of the use of toxic and harmful tetraethyl-lead (TEL) (Kazemi Shariat Panahi et al., 2019a). The TEL compound was obtained by processing ethyl chloride, a compound derived from ethanol after

Fig. 1. Methanol-derived compounds for potential use as fuel, fuel additives, and feedstock for fuel production, which include: diethylene glycol monomethyl ether (DEGME), ethylene glycol monomethyl ether (DGME), dimethylamine (DMA), dimethylamine hydrochloride (DMA-HCl), dimethylaminopropylamine (DMAPA), dimethyl carbonate (DMC), dimethyl ether (DME), dimethoxymethane (DMM), dimethylnitrosamine (DMNA), monoethylene glycol butyl ether (EGBE), monomethylamine (MMA), fatty acid methyl ester (FAME), polyisobutylene-phenolic-styrene oxide ammonium acetate (PIBP-SOAA), methyl *tert*-butyl ethers (MTBE), poly(methyl methacrylate), polyoxymethylene dimethyl ether (PODE), and *tert*-butyl alcohol.

reaction with acid. Gasoline supplemented with MTBE had a relatively greater octane rating and it was a viable alternative for other aromatic-based octane boosters such as benzene and toluene, which are toxic and carcinogenic (Olah et al., 2011; Kazemi Shariat Panahi et al., 2019a). Like all oxygenated compounds, the addition of MTBE to gasoline allows for a reduction in emissions of CO, HCs, and O₃ into the atmosphere.

Meanwhile, MTBE is synthesized by the reaction of methanol with isobutylene at about 100 °C in the presence of a mildly acidic catalyst such as polymeric acidic resins. Another compound similar to MTBE, *tert*-amyl methyl ether (TAME), is synthesized by reacting a mixture of isoamylene (IA), such as 2-methyl-1-butene (2M1B) or 2-methyl-2-butene (2M2B) with methanol in the presence of sulfuric acid (H₂SO₄) resin. The unique advantage of TAME is that it satisfies three major characteristics of reformulated gasoline fuel namely oxygenation, reduction of volatility, and elimination of photochemically reactive and volatile olefins (Arteconi et al., 2011). While substitution of a MTBE blend (2 wt.% of O₂) with an equivalent amount of TAME in gasoline resulted in similar exhaust gases (*i.e.*, CO, HC, and NO_x) emissions, VOCs and evaporative toxic air pollutants (*i.e.*, 1,3-butadiene, acetaldehyde, benzene), total toxic emissions, evaporative hot soak and formaldehyde emissions, were increased by 28% (Koehl et al., 1993).

Furthermore, dimethyl carbonate (DMC), a derivative of methanol, is a diesel additive that when combined with diesel fuel, there are improvements in emissions and performance. The DMC compound is synthesized through transesterification of ethylene carbonate with methanol. While DMC has no effect on HC emissions with its use as a fuel additive, there is a decrease in CO and NO_x emissions from combustion of

diesel as well as soot production (Lü et al., 2005; Westbrook et al., 2006). Overall, combustion of DMC-diesel blends resulted in production of less emission. Generation of particulate matters (PMs) increased when DMC was included in amounts of greater than 5% (Lü et al., 2005; Nibin et al., 2005; Arteconi et al., 2011). Diethylene glycol methyl ether (DGME) or diglyme is a diesel cetane booster and oxygenate that can be manufactured through catalytic transformation of DME and ethylene oxide at 1-1.5 MPa at a temperature of 50 to 60 °C (Mangelsdorf et al., 2002). There, however, have been many reports that DGME is a toxic compound. The major impediment for using DGME in a fuel blend is the toxicity of the compound to humans and its high critical solubility temperature that hampers miscibility with diesel resulting in phase separation even at temperatures of less than 0 °C.

Dimethoxymethane (DMM) is commercially produced by acetalization of formaldehyde and methanol at high temperatures utilizing a complicated multi-step process. Alternatively, DMM can be manufactured using a one-step selective oxidation process for methanol conversion to formaldehyde followed by acetalization of formaldehyde with another methanol molecule in the presence of an acidic catalyst (Dehghani et al., 2018). The DMM compound is a stable pro-cetane that enhances the cetane number and O₂ content of diesel that when used (at a 30% blend) results in a reduction in both NO_x and PM emissions in direct-injection diesel engines. The use of DMM-diesel blend requires no alterations in the fuel supply and combustion systems of diesel engines (Zhu et al., 2008). Zhu et al. (2008) reported that conventional diesel engines powered with DMM-diesel blend (v/v, 30%) had less CO and smoke emissions with no effect on NO_x emission.

A higher homologue of DMM, polyoxymethylene dimethyl ethers (PODE_n, $n > 1$), is available with relatively similar O₂ content but a greater cetane number and lesser vapor pressure than DMM. These desirable characteristics make PODE₃₋₅ safe green additives to diesel fuel. The PODE₃₋₅ compounds can be synthesized from the end-group (-CH₃) and chain-group (-CH₂O-) of DMM or methanol and formaldehyde or paraformaldehyde donors, respectively, in the presence of an acidic ionic catalyst, cation exchange resins, hydrochloric acid (HCl)/sulfuric acid H₂SO₄, or molecular sieves (Schelling et al., 2005; Burger et al., 2010; Qi et al., 2011; Zheng et al., 2013). Paraformaldehyde is a derivative of formaldehyde, which is commercially produced through evaporation of a 37 to 44% aqueous solution of formaldehyde in an elaborate vacuum distillation unit to prevent extensive loss of formaldehyde. The highly concentrated solution is cooled, flaked, dried, ground, and packed. Paraformaldehyde can be also produced by passing a vapor feed of high formaldehyde content (60-90% by weight of formaldehyde) through a formaldehyde-immiscible organic liquid quenching medium containing acidic or alkaline material as polymerization catalyst. The quenching medium is then fed to a settling chamber to separate the condensed and polymerized formaldehyde *i.e.*, paraformaldehyde (Sze, 1966). Hexamine or hexamethylenetetramine, a reaction product of formaldehyde and NH₃, is the main component of hexamine fuel tablet. This high-density solid fuel burns without smoke, does not liquefy when burning, and leaves no ashes.

It is commonly accepted that traditional liquid and solid rocket motors suffer from certain issues such as difficulties with thrust control and termination in these types of engines (Novozhilov et al., 2011). Although, liquid systems provide high performance, they require sophisticated and expensive plumbing. On the other hand, solid systems require uniform mixing of fuel and oxidizer, which makes them unsafe. An alternative to such systems is hybrid systems that execute combustion in diffusion mode with initial separation of fuel and oxidizer that are generally in solid and liquid states, respectively. This arrangement or its modifications provide operationally flexible and safe solution at reasonable price. Polymers can be used as solid fuels in hybrid engines. When subjected to an external heat source for sufficient length of time, polymers undergo thermal degradation with random chain cleavage, producing different products in various concentrations. Poly (methyl methacrylate) (PMMA), the polymeric form of methyl methacrylate, exhibits a heat release capacity and total heat released of 376-514 J/g/K and 23.2 kJ/g, respectively, with material melting and volatilizing so that no residues left (Novozhilov et al., 2011). The high flammability of PMMA is due to its efficient depolymerization to produce monomers (>90% yield). The complete combustion of the pyrolysis products is assisted by the O₂ of the ester group, which also contributes to the formation of low volume of smoke. To produce MMA, acetone and hydrogen cyanide are first reacted to synthesize acetone cyanohydrin. Cyanohydrin is converted to methacrylamide sulfate by H₂SO₄, which is then reacted with a methanol/H₂O mixture and heated. A process

called "Alpha" has been developed by Lucite International, which utilizes CO, C₂H₄, and methanol. The Alpha process reduces the MMA production cost by up to 40% and includes a total of three major steps; two separate catalytic reactions and a complex series of distillations in the final product separation stage. In the first step, the feedstocks are reacted in the liquid phase at 1 MPa and 100 °C in the presence of a homogeneous palladium-based phosphine ligand catalyst. The product of this step, methylpropionate, is reacted with formaldehyde in the gaseous phase over a fixed bed heterogeneous catalyst in the presence of methanol to form MMA and H₂O in the second step. MMA is then separated and purified using six distillation steps.

Isoprene is commercially produced from C₄H₈-containing C₄ fractions and formaldehyde, which includes either the gas-phase high-temperature decomposition of 4,4-dimethyl-1,3-dioxane or concurrent liquid-phase decomposition of intermediate products. The latter decomposition is performed in a column reactor in the presence of an aqueous solution of phosphoric acid (H₃PO₄) at about 160 °C and allows for a decrease in the cost of isoprene production by 1.5 times (Pavlov et al., 2011). Isoprene can be selectively oligomerized to produce a distribution of branched chain HCs. High density cyclic jet or diesel fuels can be generated by combination of an oligomerization catalyst with a metathesis catalyst. Isoprene-derived fuels exhibit performance advantages, including increased density and volumetric net heat of combustion, compared to their conventional petroleum-based counterparts (Harvey, 2016).

Furthermore, the transesterification of a large variety of vegetable oils and animal fats containing fatty acid esters with methanol leads to the formation of fatty acid methyl esters (FAME), the constituents of biodiesel, and glycerol as the main by-product (Rahimzadeh et al., 2018; Tabatabaei et al., 2019a). Biodiesel can be blended with regular diesel fuel in any proportions to reduce the emission of CO, CO₂, PM, S compounds as well as HCs that were not combusted. Limited availability of economically feasible feedstocks for the production of biodiesel continues to be a major challenge for the biodiesel industry (Hajjari et al., 2017; Rahimzadeh et al., 2018; Tabatabaei et al., 2019a). This limitation may be overcome by the production of ethylene (C₂H₄) and C₃H₆ from ethanol or methanol, which can be processed together with petroleum oil feedstocks to produce fuels with reduced GHG emissions (Olah et al., 2011).

Additionally, the energy in methanol, ethanol, and DME fuels can be converted into electrical energy through electrochemical reactions of the hydrogen fuel with an oxidizing agent in an electrochemical cell, a technology known as fuel cells. Fuels cells such as direct dimethyl ether fuel cells (DDEFC), direct ethanol fuel cells (DEFC), and direct methanol fuel cells (DMFC) are currently the prototypes that are closest to being commercially available sources of liquid fuel that may function at ambient temperature (Serov and Kwak, 2010; James et al., 2018; McDonald and Hamdan, 2019; Schechter et al., 2019). Although the time for potential scale-up and commercialization of DMFC appears to be nearing, the application of platinum (Pt) and Pt alloys on both sides of the membrane electrode assemblies makes the final fuel cell device expensive and, therefore, the competitiveness with existing technologies is questionable. The toxicity, high flammability, ease of crossover of methanol from the anode to the cathode side of the fuel cell device are other impediments for large scale DMFC commercial development. In recent decade, there has been a newer type of fuel cell developed that has the capacity for operation with polyols as an energy source, which have some advantages when compared to the use of methanol in fuel cells (Serov and Kwak, 2010; Lamy and Coutanceau, 2012). Some of the advantages of polyol use include a 17% greater theoretical capacity (4.8 against 4 Ah/mL for methanol) and higher boiling point (198 compared to 65 °C for methanol), and consequently, greater safety. Furthermore, each C of EG and glycerol carries an alcohol group, the partial oxidation of which to oxalate and mesoxalate in alkaline medium and oxalic and mesoxalic acids in acid medium without CO₂ or carbonate ion (CO₃²⁻) emission, *i.e.*, without C-C bond breaking, exchanges eight and 10 electrons, respectively. In contrast, their complete oxidation to CO₂ or CO₃²⁻ involves 10 and 14 exchanged electrons for EG and glycerol, respectively, against six electrons during complete oxidation of the simplest alcohol, *i.e.*, methanol, to CO₂. This property allows the utilization of up to 80% of whole energy available in these compounds without breaking C-C bonds.

3. Ethanol

3.1. Background and possibilities

Ethanol, a biofuel, is the only alcohol that is used as human beverage unless it is denatured. The use of ethanol as an illuminant in lamp oil as well as heating source dates back to the 17th century (Kazemi Shariat Panahi et al., 2019a). Thereafter, ethanol was used as fuel in the first American ICE prototype designed by Samuel Morey and that designed by the German engineer, Nikolaus August Otto, in 1826 and 1860, respectively (Cummins, 1989; Hardenberg and Morey, 1992; Kazemi Shariat Panahi et al., 2019a). In 1896, Henry Ford and colleagues built their first quadricycle automobile that had an ethanol-powered engine (Kazemi Shariat Panahi et al., 2019a). Since that time, various ethanol blends have been used in different types of gasoline-powered vehicles (Balat et al., 2008; Kazemi Shariat Panahi et al., 2019a). Numbers of gasoline-powered automobiles that were built exceeded those of the alcohol-powered counterparts mainly due to discovery of oil deposits that led to gasoline being at an economically competitive advantage in countries with oil deposits as compared to use of ethanol as a fuel source.

The circumstances of World Wars and oil crises due to trade barriers highlighted the importance of the alcohol industry for energy independence and sustainability (Kazemi Shariat Panahi et al., 2019a). Indeed, interests in using ethanol as a transportation fuel were revived in the 1970s due to an increase in oil prices as a result of international trade impediments, simplicity and availability of ethanol production and distillation technologies, as well as compatibility of ethanol with ICE (Olah et al., 2011; Kazemi Shariat Panahi et al., 2019a). More specifically, ethanol provides for a greater compression ratio, shorter burn time, and greater lean burn in ICE than gasoline. These advantages (Table 3) result from the broader ethanol flammability, higher octane number, greater flame speeds and heats of vaporization (MacLean and Lave, 2003). It is worth to mention that octane number is a standard measure of quality that indicates anti-knock properties of a given fuel. The higher the octane number, the less is the susceptibility of the fuel to explosion due to premature burning in the cylinder. Ethanol, however, has only 65% of the energy density of gasoline (albeit 25% greater energy content than methanol), lesser vapor pressure (making “cold starts” difficult), and lesser flame luminosity (MacLean and Lave, 2003). Other disadvantages of ethanol include corrosiveness and unlimited miscibility with water (MacLean and Lave, 2003; Rahimpour et al., 2019). While engine “cold starting” can be greatly improved by blending ethanol with gasoline, the increase in the volatility of ethanol (Reid vapor pressure) can result in increase in evaporative emissions after combustion (MacLean and Lave, 2003).

Currently, ethanol is used as a fuel or gasoline extender, also known as gasohol and octane booster. It is used in reformulated fuel programs to oxygenate gasoline in winter months, replacing MTBE. Traditionally, ethanol is blended with gasoline (5.7%, v/v) to generate 2% by weight of O₂ but currently, 7.7% to 10% ethanol is blended with gasoline (Kazemi Shariat Panahi et al., 2019a). In the USA, gasohol or E10 is a blend of gasoline and ethanol at the ratio percentage of 90:10 (v/v) whereas gasohol in Brazil contains a greater amount of ethanol (24%, v/v) (Dias De Oliveira et al., 2005). Indeed, in flexible fuel vehicles (FFVs), which have port fuel injection type of engines and a spark ignition system, gasoline-ethanol blends with ethanol contents as high as 85% (E85) can be used as a fuel (MacLean and Lave, 2003). Gasoline-ethanol blend programs have been developed in countries other than the USA including Australia, Canada, China, Columbia, India, Paraguay, Peru, Sweden, and Thailand (Balat et al., 2008).

Approximately 80% of the global production of ethanol comes from fermentations while the remaining 20% comes from chemical synthesis via hydration of C₂H₄ from natural gas and petroleum. In 2018, total global ethanol production was approximately 108.14 billion L mainly from corn and sugarcane fermentations that was about a 118% increase in production when compared to the amount produced in 2007 (Fig. 2). The total amount of biofuel production reached 143 billion liters in 2017 (~9 times increased compared to its production in 2000) with the ethanol as the largest biofuel (accounting for about 95% of global biofuel production in 2008) (Balat et al., 2008; WBA, 2018). The world leading fuel bioethanol producers are the USA and Brazil producing more than 85% of the total amount of bioethanol produced globally from 2007 to 2018 (AFDC, 2018; RFA, 2019). China is the fourth largest

Table 3.
Fuel properties of ethanol.

Chemical formula	C ₂ H ₆ O
Structure
Molar mass (g/mol)	46.068
Boiling point (°C)	78.37
Melting point (°C)	-114.1

Research octane No.	108.6

ethanol producer with the amount produced being only 2.7% of the global ethanol production in the same period (AFDC, 2018). However, China improved its production share in 2018 reaching 4% of global fuel ethanol while the USA and Brazil roughly kept the similar global share as 2007-2018 (i.e., 84%) (RFA, 2019) (Fig. 2). This marked difference in productivity between USA-Brazil and China may be due to feedstock availability and cost. The abundance of sugarcane and corn in Brazil and the USA, respectively, appear to facilitate the production of bioethanol in both countries.

3.2. Chemical synthesis of ethanol

Ethanol can be manufactured through chemical synthesis by hydration of C₂H₄ from natural gas, syngas, and cracking of crude oil. The substrate, C₂H₄, is converted to ethanol using steam and a catalyst, which often results in generation of toxic by-products and requires purification to remove undesirable by-products and H₂O. The utilization of C₂H₄ for ethanol

production is unattractive due to the crude oil prices; however, use of lignocellulosic biomass and coal as feedstocks for chemical synthesis of ethanol is generating some interests. The lignocellulosic biomass and coal feedstocks can be converted into ethanol through use of three methods (Subramani and Gangwal, 2008): (i) gasification of lignocellulosic biomass and coal to syngas, followed by direct conversion of syngas into ethanol in a process that involves selective hydrogenation of CO to ethanol in the presence of a catalyst; (ii) conversion of syngas (*i.e.*, CO, and H₂) into methanol followed by methanol homologation, which involves reductive carbonylation of methanol in the presence of a redox catalyst, a C-C bond formation process, to generate ethanol; and (iii) a multistep ENSOL process, in which syngas is first transformed into methanol in the presence of a commercial methanol synthesis catalyst, followed by carbonylation of methanol into acetic acid in the second step, and hydrogenation of acetic acid to ethanol. While methanol homologation and ENSOL processes for chemical synthesis of ethanol have been scaled up to pilot scale (Subramani and Gangwal, 2008), both technologies are plagued with product yields in small amounts and selectivity, and high operating cost due to the great amount of energy consumption and use of expensive catalysts such as Rh.

3.3. Microbial production of ethanol

Commercial fermentative production of ethanol has a long history and is a common practice, which is mainly dependent on edible source of sugar or starch. However, fuel application of this ethanol also known as the first generation bioethanol has sparked severe debates on its sustainability aspects including its adverse impacts on food availability as well as the prices of food commodities. Therefore, efforts have been put in developing the second generation ethanol from lignocellulosic feedstocks.

3.3.1. Ethanol-producing microorganisms

Native and engineered strains of microorganisms used for ethanol production are the ethanologens: *Candida brassicae*, *Candida shehatae*, *Clostridium sordelli*, *Clostridium sphenoides*, *Clostridium sporogenes*, *E. coli*, *Erwinia amylovora*, *Klebsiella aerogenes*, *Klebsiella oxytoca*, *Kluyveromyces fragilis*, *Mucor indicus*, *Pachysolen tannophilus*, *Pichia stipitis*, *Saccharomyces cerevisiae*, *Spirochaeta aurantia*, *Spirochaeta litoralis*, *Spirochaeta stenostrepta*, and *Zymomonas mobilis*. Efficient ethanologenic microorganisms can be precisely described based on values for fermentation performance variables such as ethanol production and tolerance (>40 g/L), genetic stability, inhibitor tolerance, growth rate, tolerance towards osmotic stress/more acidic pH/higher temperature values, productivity (>1 g/L/h) and yield (>90% of theoretical), and specificity range (Dien et al., 2003; Balat et al., 2008). Some common and efficient ethanologenic microorganisms along with the advantages and limitations associated with their use are reported in Table 4.

Although the use of *S. cerevisiae* for ethanol production from starch derived sugars and sugarcane derived sucrose has been commercially dominant, the opposite is the case for sugars derived from lignocellulosic feedstocks. Even though there is a long history and great characteristics of *S. cerevisiae* for ethanol fermentation, the wild-type *S. cerevisiae* does not metabolize xylose. This limitation is significant because xylose is the second most common fermentable sugar after glucose in lignocellulose hydrolysates. Consequently, the yield of ethanol from lignocellulosic hydrolysate is poor when the biocatalyst is *S. cerevisiae*, thus, highlighting the need for the generation and use of engineered *S. cerevisiae* with improved xylose metabolism characteristics for ethanol fermentation with lignocellulosic biomass hydrolysates (Matsushika et al., 2009). Currently, *E. coli*, *K. oxytoca*, and *Z. mobilis* are the most promising bacteria for commercial production of ethanol (Alia et al., 2019; Kumar et al., 2019). *E. coli* and *K. oxytoca* are the first two species that can utilize a broad range of substrates including pentose and hexose sugars. Native forms of these bacteria, however, do not function to produce ethanol selectively (Table 4). In contrast, *Z. mobilis* can quickly uptake sugars and is not inhibited by high concentrations of ethanol. The major impediment for the commercial application of this microorganism in production of ethanol is its narrow-range of substrate and the production of high concentrations of by-products (Table 4). Interestingly, *Z. mobilis* is the only microorganism that metabolizes glucose anaerobically via the Entner-Doudoroff (ED) instead of the glycolytic or Embden-Meyerhoff-Parnas pathway (Dien et al., 2003).

Compared to *Z. mobilis*, there is utilization by *E. coli* of pyruvate formate-lyase and lactate dehydrogenase to channel pyruvate toward a mixture of fermentation products such as ethanol, acetic acid (AA), lactic, succinic, and formic acid. Notably, the key issue in fermentation is the regeneration of the oxidized form (NAD⁺) of NADH so that glycolysis may be sustained. With use of *E. coli*, therefore, there is generation of by-products such as AA and succinic acid (SA) to maintain the redox balance during growth and fermentation (Dien et al., 2003).

There are basically two approaches to increase utilization of pentose sugars and improve ethanol production from lignocellulosic feedstock (Dien et al., 2003; Jeffries and Jin, 2004). With the first approach, there is the aim to introduce the pentose metabolic pathway into ethanologens that lack the capacity to metabolize pentose sugars whereas with the second approach the aim is to improve ethanol yields in microorganisms with the natural capacity to ferment both 5- and 6-C sugars to ethanol. To facilitate metabolic modifications in fermenting microorganisms and enhance pentose sugars utilization as well as ethanol productivity and yield, functional genomics including transcriptomics, proteomics, metabolomics, and fluxomics have been utilized. More specifically, these fields of molecular biology provide very useful approaches in understanding the in-depth physiology of these microorganisms as well as making relevant metabolic alterations for improvements in microbe functionality for these fermentation purposes (Matsushika et al., 2009). Recently, more sophisticated and efficient approaches for genome editing such as CRISPR/Cas9 are being used to modify *Z. mobilis* and other fermenting microorganisms to enhance fermentation performance (Borodina and Nielsen, 2014; Yang et al., 2016).

3.3.2. Commercial fermentative production of ethanol

The first demonstration lignocellulosic ethanol plant has been in operation in Canada since 2004 (Tampier et al., 2004). Since then many pilot or commercial lignocellulosic ethanol plants have been constructed and are in operation in different parts of the world. In the SEKAB Company located in Ornskoldsvik, Sweden, there is use of acid (*i.e.*, H₂SO₄ or SO₂) and steam pretreatment (*i.e.*, 200 °C) technologies to de-lignify lignocellulose and release hemicellulose derived sugars from wood chips and sugarcane bagasse. Subsequently, solid residues (*i.e.*, cellulose and lignin) are separated and subjected to enzymatic hydrolysis to release the remaining sugars from the cellulose component of the solid residue. The low pH slurry (containing pentose and hexose sugars) is neutralized and subjected to simultaneous saccharification and fermentation (SSF) or separate hydrolysis and fermentation (SHF) to produce ethanol using recombinant *S. cerevisiae*. At the end of the process, ethanol is recovered by use of a distillation process while solid residues, mainly lignin, are used as a biofuel or are refined into other products. Remnants of ethanol fermentation, solubles or extractives, may be degraded by microorganisms for production of biogas, which may be used for energy generation in the ethanol plant or marketed to power plants to generate additional revenues (<http://www.sekab.com/biorefinery/e-tech-process/>).

Some lignocellulose-based ethanol plants that are currently operating or have operated in the past at pilot or commercial scales include: Abengoa in Hugoton, KS (enzymatic hydrolysis of corn stover to ethanol); Beta Renewables in Sampson County, NC (enzymatic hydrolysis of arundo and switchgrass to ethanol); DuPont Biofuel Solutions in Nevada, IA (enzymatic hydrolysis of corn stover to ethanol); and POET in Emmetsburg, IA (enzymatic hydrolysis of corn stover and corn cobs to ethanol). Currently, breakdown of lignocellulose to sugars and subsequent fermentation to ethanol costs as much as three times more than sugar- and starch-containing feedstocks when capital costs are considered. Additionally, the economic cost for current technology for delignification of lignocellulose and hydrolysis of cellulose to fermentable sugars cannot be offset by the lesser economic cost of lignocellulose as a feedstock. It, however, is envisaged that knowledge gained from the commercial/pilot plants that are currently operational with regard to cost, feedstock handling and logistics, product yield and productivities, challenges and proffered solutions, will be eventually be used to help reduce production cost of cellulosic-produced ethanol.

Table 4.
Advantages and limitations of ethanologens for commercial production of bioethanol.

Microorganism	Advantages	Limitations	Reference
Yeast			
<i>Saccharomyces cerevisiae</i>	<ul style="list-style-type: none"> -High bioethanol production from 6-carbon sugars -High tolerance to inhibitors ($\geq 10\%$ v/v, ethanol included) such as compounds in the acid hydrolysates of lignocellulosic feedstocks -Application of residual cell mass as animal feed additive -Commercial application for non-lignocellulosic feedstocks -GRAS^a -High alcohol yield (typically 90%) -Amenability to genetic engineering 	<ul style="list-style-type: none"> -Unable to consume 5-carbon sugars, such as arabinose and xylose -Unable to consume celloligosaccharides -Inadequate yield of ethanol from lignocellulosic hydrolysates -Susceptible to high temperatures of enzyme hydrolysis (in case of SSF) 	<p>Hahn-Hägerdal et al. ^a Generally recognized as safe

- Fermentation of lignocellulosic biomass and product recovery

Thermotolerant microorganisms capable of generating optimal ethanol yields and productivity, tolerating high ethanol titers and lignocellulose derived microbial inhibitory compounds such as furfural, hydroxymethyl furfural (HMF), ferulic acid, vanillin, and coumaric acid in fermentation broth, are ideal for lignocellulose-based bioethanol industry (Ezeji et al., 2007; Okonkwo et al., 2016). Indeed, different processes and metabolic engineering strategies are being developed to facilitate complete utilization of sugars present in lignocellulosic biomass hydrolysates and conversion into target products such as ethanol (Sarkar et al., 2012; Kazemi Shariat Panahi et al., 2019a). Based on the enzymatic-fermentation approach, the fermentation of pretreated lignocellulosic feedstocks can be performed by either using SHF or SSF (Table 5). The use of unconventional method, SSF, allows for generation of desirable yields of ethanol because sugars generated by enzymes are fermented to ethanol in real-time, thereby alleviating end-product inhibition by cellobiose, glucose, and xylose during enzymatic hydrolysis of pretreated

lignocellulosic feedstocks (Kazemi Shariat Panahi et al., 2019b). Sub-optimal temperatures for cellulase activity, however, are typically imposed for SSF processing involving *S. cerevisiae* and *Trichoderma reesei* derived cellulase with an optimal temperature for activity being 55 °C. The SSF is typically performed at 37°C to improve cellulase activity at this temperature resulting in lesser ethanol tolerance and greater distillation costs due to the relatively lesser ethanol concentration in the fermentation broth (Hamelinck et al., 2005). While bacteria function is optimal at a narrow pH range of 6.0 and 7.5, fungi and yeast function at a wider pH range and tolerate an acidic pH as low as 3.5 (Aminfarshidmehr, 1996). In contrast, optimal temperature conditions for cellulase enzymes for hydrolysis of pretreated lignocellulose and fermentation of reducing sugars to ethanol can be applied conveniently with conventional methods (*i.e.*, SHF) (Bjerre et al., 1996; Hamelinck et al., 2005; Kazemi Shariat Panahi et al., 2019b). For example, cellulase preparations obtained from *T. reesei* have an optimal activity at pH 4.5 and 55 °C. To mitigate disparity in the SSF process conditions and enhance ethanol productivity, there should be

Table 5.

Advantages and limitations of separate hydrolysis and fermentation (SHF) or simultaneous saccharification and fermentation (SSF) for production of ethanol.

Configuration	Advantages	Limitations
SHF ^a	<ul style="list-style-type: none"> -Minimized inter-steps interactions -Optimum operating condition for each step 	<ul style="list-style-type: none"> -Lower yields of reducing sugar due to end-product inhibition -Higher chance of contamination due to prolonged process -Higher costs and higher enzyme consumption -Two-stage bioethanol production from pentose and hexose sugars at different reactors
SSF ^b or SSCF ^c	<ul style="list-style-type: none"> -Lower costs -Reduction in the number and the volume of the required reactors -Overcoming the end-product inhibition of saccharification step -Higher yields of hydrolysis with lower enzyme requirement -Higher yields of ethanol (about 5 wt.%) -Lower requirement for sterile conditions due to immediate consumption of generated glucose for bioethanol production -Shorter process time -Simultaneous consumption of pentose and hexose sugar at a same reactor (SSCF) 	<ul style="list-style-type: none"> -No optimum temperature conditions for the best results of both saccharification and fermentation can be reached at the same time. -Low pH (<5) and high temperature (>40°C) which is favorable for enzymatic hydrolysis can inhibit the formation of lactic acid and may adversely affect the yeast cell growth

^a Separate hydrolysis and fermentation^b Simultaneous saccharification and fermentation^c Simultaneous saccharification and co-fermentation

use of thermotolerant microorganisms such as *Candida lusitanae*, *Kluyveromyces marxianus*, or *Z. mobilis* for the fermentation of generated sugars to ethanol (Bjerre et al., 1996; Hamelinck et al., 2005; Balat et al., 2008; Sarkar et al., 2012; Kazemi Shariat Panahi et al., 2019a and b). These microorganisms, however, are not as robust and ethanologenic as *S. cerevisiae*.

The SSF process involves simultaneous fermentation of 5- and 6-carbon sugars with a process termed simultaneous saccharification and co-fermentation (SSCF) (Kazemi Shariat Panahi et al., 2019b). The SSCF process is efficient and designed to sustain glucose concentrations in the bioreactor low, reduce catabolite repression of microbial function, and enhance xylose conversion into target products (Liu and Chen, 2016). While little to no data from a pilot scale plant are available, there is a closely related process known as consolidated bioprocessing (CBP) or direct microbial conversion (DMC) in which cellulase production, hydrolysis of pretreated lignocellulosic feedstock, and ethanol fermentation take place in a single reactor (Bjerre et al., 1996; Kazemi Shariat Panahi et al., 2019b). Microorganisms such as *Aspergillus* sp., *Clostridium thermocellum*, *Fusarium oxysporum*, *Neurospora crassa*, *Paecilomyces* sp., and *Zygosaccharomyces rouxii*, have been used either in mono- or co-culture forms in CBP processes. Although CBP is less capital intensive than the conventional process due to savings from enzyme purchases, the process is not efficient because of the long fermentation time (3-12 d), small ethanol concentrations (0.8-60 g/L), and large amounts of unwanted by-products such as AA and lactic acid (LA) (Szczo drak and Fiedurek, 1996; Kazemi Shariat Panahi et al., 2019b). As a result, the pilot plant based on CBP configuration operated by Mascoma Corporation headquartered in Lebanon New Hampshire, USA, with a capital cost of USD 232 million to turn hardwood pulp directly to ethanol is sub-optimal as compared to the installation capacity. Some examples of conversion of various lignocellulosic feedstocks to ethanol using CBP processing configurations are presented in Table 6.

3.4. Ethanol derivatives as fuel components: production, applications, and performance

Although ethanol is a fuel additive for gasoline, its hygroscopic nature creates problems during transportation, especially in moist environments such as marine motor fuels. While ethanol has been transported via pipelines in the USA and Brazil, its corrosive nature and tendency to absorb water and impurities in the pipelines often result in excessive corrosion of the pipeline system. Use of stainless steel pipes has been recommended as a viable strategy to mitigate corrosion in fuel pipelines that are used to transport ethanol and gasoline-ethanol blend fuels. Even stainless steel pipelines, however, have stress corrosion cracking after use for a considerable length of time. Consequently, gasoline is blended with ethanol in a designated facility and transported to dispensing gas (filling) stations using tanker trucks. Cost

effective conversion of ethanol to other fuel chemicals (Fig. 3), however, may be a more effective strategy for addressing ethanol induced corrosion problems.

Ethanol can either be acid esterified or dehydrated in the presence of a Cu catalyst at high temperatures to generate ethyl acetate, which has a greater heat of combustion than ethanol (Jones, 2011). The stability and octane rating of gasoline-ethanol blends (with ethanol contents as high as E20) is considerably improved by the addition of ethyl acetate (Amine et al., 2017). The addition of other esters such as iso-butyl acetate, *n*-butyl acetate, or methyl acetate to gasoline resulted in improvement of its octane number and oxidation stability. This is a desirable characteristic that contributes to an enhancement in fuel storage capacity and stability of fuel vapor pressure (Amine et al., 2013; Dabbagh et al., 2013). Notably, with use of these esters, there is a reduction in emissions of aldehydes, CO, and ketones due to the high oxidation state of these compounds allowing for use in automobiles with no requirements for engine modifications (Dabbagh et al., 2013).

Ethanol can also be converted into C₂H₄ in the presence of an alumina-based catalyst in a tubular fixed bed reactor at a temperature range between 240 and 450 °C or with addition of TiO₂/Al₂O₃ catalysts in a microchannel reactor (Chen et al., 2007; Morschbacker, 2009; Kagymanova et al., 2011). The produced C₂H₄ could then be converted into several fuel additive compounds such as diethanolamine (DEA), EG, glycerol, and glycol ethers (Fig. 3). Notably, fuel lubricating and anti-wear additives have been made from DEA or its derivatives for diesel or biodiesel fuels (Ball et al., 1999; Jung et al., 2016; Lagona and Loper, 2017; Levine et al., 2018). Glycol ethers are potential fuels that react with alcohols such as butanol, ethanol, methanol, or phenol, generating products with excellent fuel additive properties. An investigation by Gómez Cuenca et al. (2011) on effects of ethylene glycol ethers such as monoethylene glycol ethyl ether (EGEE) and diethylene glycol ethyl ether (DEGEE) on diesel fuel properties and emissions in diesel engines revealed that the addition of these compounds to fuels at 4 wt.% (v/v) improved both lubricity and viscosity of diesel fuel. While the inclusion of EGEE resulted in a decrease in the cetane number of the diesel fuel, the inclusion of DEGEE increased the number.

The MTBE compound used to be preferred for oxygenating gasoline due to its superb vaporization properties, however, the relatively greater solubility of MTBE in H₂O and slow degradation in the environment detracted its use and resulted in increased use of bioethanol and its derivative, ethyl tert-butyl ether (ETBE), as oxygenated additives for gasoline (Olah et al., 2011; Kazemi Shariat Panahi et al., 2019a). The reaction of isobutylene with ethanol in the presence of an acid catalyst results in the production of ETBE. The reaction, however, is reversible and when this occurs, there is a side reaction involving dimerization of isobutylene and production of diisobutene (François and Thyron, 1991).

4. Butanol

4.1. Background and possibilities

Butanol is a colorless four-carbon alcohol with a characteristic banana-like odor. The high energy content of butanol, its hydrophobicity and flash point, make it a potential substitute for gasoline and diesel as fuel sources. The other desirable qualities of this C₄-liquid energy source includes: low volatility, miscibility, and octane-enhancement property (Schwarz and Gapes, 2006). The relatively greater heat of evaporation for butanol results in a lesser combustion temperature and reduced NO_x emissions relative to many other energy sources (Rakopoulos et al., 2010). The branched forms (isomers) of butanol such as 2-methyl-1-butanol, 3-methyl-1-butanol, and isobutanol also have high octane numbers and desirable fuel and fuel additive properties (Atsumi et al., 2008b). The fuel properties of butanol isomers are provided in Table 7, some of which are superior to that of ethanol (Table 3), methanol (Table 2), or gasoline (Table 1).

A major limiting factor for the use of biobutanol as biofuel, however, is its low concentration in the bioreactor during acetone butanol ethanol (ABE) fermentation, which is 8 to 18 times less than that of ethanol produced by yeast fermentation. The low butanol concentration in the fermentation broth upon completion of ABE fermentation is due to butanol toxicity to the fermenting microbes at low concentrations (<1.5%). This impediment is probably the major reason why ethanol is still the liquid biofuel that continues to be most commercially available. Advances in metabolic engineering techniques have pushed commercialization of the fermentative production of butanol. However, further research in the areas of non-food substrates application, process optimization, and product recovery are still needed to sustain current commercialization efforts (Greene, 2004; Meadows et al., 2018). Butanol produced from fossil fuels and gases is presently commercially available as a solvent and for the production of butyl acrylate which is a primary chemical feedstock used for the production of water-based paints.

4.2. Chemical synthesis of butanol

Crotonaldehyde hydrogenation, oxo synthesis (hydroformylation), and Reppe synthesis (Fig. 4) are the three major chemical processes for butanol synthesis. Prior to 1950s, crotonaldehyde hydrogenation of acetaldehyde to butanol was the common production process. The crotonaldehyde hydrogenation process involves an aldo condensation of acetaldehyde at ambient temperatures and pressure in the presence of alkaline catalysts, which is followed by dehydration as a result of acidification with AA or

Fig. 4. Chemical synthesis of butanol using the three major processes: (a) crotonaldehyde, (b) oxo synthesis, and (c) Reppe synthesis.

H_3PO_4 . The resulting compound, crotonaldehyde, is distilled followed by hydrogenation at the gaseous or liquid phases in the presence of a Cu catalyst. Compared to hydroformylation and Reppe synthesis, crotonaldehyde hydrogenation does have complete reliance for a petroleum feedstock although biomass-derived ethanol can be used as feedstock. Thus, ethanol can be dehydrogenated into acetaldehyde as the starting feedstock for the crotonaldehyde hydrogenation process for butanol synthesis (Cotton et al., 1999; Lee et al., 2008; Uyttebroek et al., 2015). The invention of the oxo synthesis process, a variation of Fischer-Tropsch (FT) process of Ruhrchemie's Roelen, led to the demise of the use of the crotonaldehyde hydrogenation process because the oxo process is economically less expensive and more efficient from a productive perspective. The first step of oxo process of chemical butanol synthesis is the reaction between petroleum-derived olefins such as C_2H_4 and propylene (C_3H_6) and carbon monoxide (CO) in the presence of Rh or Ru catalyst for the production of intermediate compounds (aldehydes) with a formyl group (CHO). The generated aldehydes have one more C atom than the starter compound, i.e., olefin. This process can be energy consuming as it is conducted at high temperatures (80–200 °C) and pressures (20–30 MPa) depending on the type of catalyst used. Following the production of the aldehyde mixture (1-butanal and 2-methylpropanal) in the first step of the reaction, the second step involves hydrogenation of the aldehydes in liquid or vapor phase using Cu, Ni, or the combination of the two to the corresponding alcohols (25% 2-methyl-1-propanol or isobutanol and 75% 1-butanol) (O'Rourke et al., 1981).

The leading producers of butanol using this process are BASF, Dow Chemical Company, and Oxea Group (Uyttebroek et al., 2015). Furthermore, the Reppe process was developed in 1942 and involves carbonylation of C_3H_6 using CO and H_2O with inclusion of a catalyst (tertiary ammonium salt or polynuclear iron carbonyl hydrides) at 0.5 to 2 MPa and 100 °C to produce 1-butanol (Cotton et al., 1999; Uyttebroek et al., 2015). During the process, 1-butanol and isobutanol are directly generated in a ratio of 43:7. Even though Reppe process has relatively moderate reaction conditions and generates greater yield of 1-butanol than with the oxo process, the Reppe process has not been commercially implemented because the process is economically impractical.

4.3. Butanol-producing microorganisms

Solventogenic *Clostridium* is best known for natural capacity to produce butanol (Lee et al., 2008; Ujor et al., 2016; Xin et al., 2018). Approximately 40 solventogenic *Clostridium* strains are available in public culture collections, an

enormous pool of strains and resource for screening novel traits such as solventogenic *Clostridium* strains are available in public culture collections, an enormous pool of strains and resource for screening novel traits such as utilization of alternative substrates for butanol production, phage resistance, and hyper solvent-producing capacity (Zverlov et al., 2006). It is worth noting that with use of these strains, a combination of solvents, often including acetone, butanol, and ethanol could be produced. *Clostridium acetobutylicum* ATCC 824 and *Clostridium beijerinckii* NCIMB 8052 are the most studied solventogenic *Clostridium* species. *Clostridium saccharobutylicum* and *Clostridium saccharoperbutylacetoni* have been receiving attention recently for the production of large amounts of butanol during ABE fermentation (Dürre, 2005; Dong et al., 2018; Huang et al., 2018; Foulquier et al., 2019). *Clostridium* species such as *Clostridium ljungdahlii* and *Clostridium butyricum* have the capacity to utilize syngas and hemicellulose, respectively, for acetone and butanol production (Montoya et al., 2001). Through metabolic engineering, aerobic and/or facultative microorganisms such as *Bacillus subtilis*, *E. coli*, *S. cerevisiae*, and *Bacillus* sp., 15 have been developed to produce large amounts of solvents (Atsumi et al., 2008a, 2008b; Inui et al., 2008). Indeed, with use of *Bacillus* sp. 15, large amounts of butanol (12.3 g/L), acetone (5.05 g/L) and ethanol (0.115 g/L) titers (Ng et al., 2016) could be produced comparable to those of solventogenic *Clostridium* species. While this research has not been replicated by an independent laboratory, the quest appears to be feasible for the development of a suitable aerobic platform for the production of butanol. Meanwhile, the cost of butanol recovery from fermentation broth is the second largest contributor to biobutanol production cost (about 16%), the first being substrate cost, due to the formation of mixed solvents and the low butanol titer in ABE fermentation.

4.3.1. Butanol fermentation: challenges

The lack of butanol tolerance by fermenting microorganisms has been identified as the major factor that causes the lesser cell density and premature termination of fermentation during butanol production by solventogenic *Clostridium* microbes. To mitigate this problem, several strategies such as metabolic engineering of microorganisms for improved butanol tolerance and production, and *in-situ* real-time butanol recovery to reduce solvent toxicity to the microorganisms and enhance butanol production have been proposed (Annous and Blaschek, 1991; Green et al., 1996; Harris et al., 2001; Tomas et al., 2003; Lee et al., 2008; Ezeji et al., 2010).

4.3.1.1. Metabolic engineering of fermenting microorganisms

Genetic improvements of ABE-producing strains generally include one of two approaches: (i) enhancement of ABE tolerance in solventogenic *Clostridium* spp. and (ii) metabolic engineering of well-characterized microorganisms such as *E. coli* and *S. cerevisiae* for ABE production (Ezeji et al., 2010). The overarching objective of these methods is to produce greater titers of butanol during fermentation. Notably, increasing the concentration of butanol from 10 to 40 g/L results in a 6-fold decrease in the amount of oil (energy) required to recover butanol from fermentation broth. Genetic strain improvement of solventogenic clostridia such as *C. acetobutylicum* and *C. beijerinckii* for greater solvent tolerance, production, and yield, and development of non-native butanol producing microorganisms as platforms for producing butanol are included in Table 8. Although native butanol producing solventogenic *Clostridium* microbes have some inherent advantages such as capacity to utilize a wide range of substrates and production of multiple products, there are also some inherent limitations of these microbes such as their obligate anaerobic nature, slow growth rates, and less tractability in terms of genetic engineering when compared to well-characterized microorganisms such as *E. coli*, *B. subtilis*, and *S. cerevisiae*. Development of well-characterized microorganisms such as *E. coli* and *S. cerevisiae*, therefore, as viable platforms for butanol production are being considered (Ezeji et al., 2010). Recently, microorganisms that have a natural capacity to tolerate relatively greater concentrations of butanol than the native butanol producers have been considered as viable platform for producing butanol (Table 8, section c).

Table 8.
Amelioration of solvent toxicity in acetone- and butanol-producing microorganisms with genetic strain improvements.

Mutated Strain	Strain used for mutation	Method	Achievements	Reference
a. Strategy: Enhancing ABE^a resistance in solventogenic clostridia				
SA-1	<i>Clostridium acetobutylicum</i> ATCC 824	Serial transfer into fresh media with increasing concentrations of 1-butanol.	-Higher butanol tolerance (121%) -No increase in butanol yield	Lin and Blaschek (1983)
SA-2			-Higher butanol tolerance (27%) -No increase in butanol yield	Baer et al. (1987)
PJC4BK	<i>C. acetobutylicum</i> ATCC 824	Inactivation of butyrate kinase	-Higher butanol production (28%) -Enhance solvent tolerance	Green et al. (1996)
SolRH	<i>C. acetobutylicum</i> ATCC 824	Inactivation of solvent formation repressor <i>solR</i>	Higher ABE production (25%, 14%, and 81%, respectively, for butanol, acetone, and ethanol)	Nair et al. (1999) Harris et al. (2001)
SolRH (pTAAD)	<i>C. acetobutylicum</i> strain SolRH	Overexpression of the alcohol dehydrogenase gene <i>aad</i>	-Higher ABE production (21%, 45%, and 62%, respectively, for butanol, acetone, and ethanol) -Produced 17.6 and 8.2 g/L butanol and acetone, respectively	Harris et al. (2001)
pGROE1	<i>C. acetobutylicum</i> ATCC 824	Overexpressing of genes in the class I stress response operon <i>groESL</i>	-Less growth inhibition from butanol (85%) Production of 17.1 g/L butanol and 8.6 g/L acetone. -Longer active metabolism -Increased expression of motility and chemotaxis genes -Decreased expression of main stress response genes	Tomas et al. (2003)
pCAC0003 and pCAC1869	<i>C. acetobutylicum</i> ATCC 824	Genomic library Plasmids were inserted into wild type <i>C. acetobutylicum</i> cells via electroporation, and the cells were challenged with various amounts of butanol	Sixteen genes were identified as contributing to the cells ability to withstand greater concentrations of butanol pCAC0003 and pCAC1869 showed a 24%- and 45%- increase in tolerance	Borden and Papoutsakis (2007)
BA101	<i>Clostridium beijerinckii</i> NCIMB 8052	Direct mutation with N-methyl-N-nitro-N-nitrosoguanidine	-Higher solvent production than any <i>C. acetobutylicum</i> strain engineered at that time -Good stability -Hyper-amyolytic and hyper-butanogenic (up to 19 g/L) characteristics -Total solvent concentration of 29 g/L -Higher butanol production (2×) and threshold (2.1×) than wild type strain	Annous and Blaschek (1991) Qureshi and Blaschek (2001)
b. Strategy: Metabolic engineering of well-characterized microorganisms				
ATCC 11303 (pACT)	<i>Escherichia coli</i>	Expression of four <i>C. acetobutylicum</i> ATCC 824 genes (<i>adc</i> , <i>ctfA</i> , <i>ctfB</i> , and <i>thl</i>)	Higher acetone production (5.4 g/L) comparable to wild type <i>C. acetobutylicum</i>	Bermejo et al. (1998)
JCL16	<i>E. coli</i>	-Overexpression of KDCs ^b and ADHs ^c -Metabolic engineering of amino acid biosynthetic pathway to enhance the production of the specific 2-keto acid for improvement of desired alcohol production -Deletion of genes corresponding to competing reactions -Replacement of some native <i>E. coli</i> genes with more active genes from other hosts	-High-yield, and high-specificity production of isobutanol (22 g/L) from glucose	Atsumi et al. (2008b)
NA ^d	<i>Saccharomyces cerevisiae</i> ^e	Cloning the 1-butanol pathway and various isozymes selected from <i>C. beijerinckii</i>	Production of 2.5 mg/L of 1-butanol	Steen et al. (2008)
c. Strategy: Solvent-resistant microorganisms as potential acetone-butanol production hosts				
S12	<i>Pseudomonas putida</i>	Adaptation by serial transfer	Capable of growth on 6% butanol	Rühl et al. (2009)
PS1.0 PS2.0	<i>P. putida</i> strain S12	Polycistronic expression of butanol biosynthetic genes	-Production of 44 and 50 mg/L butanol, respectively, when grown on glucose -Production of 122 and 112 mg/L butanol, respectively, when grown on glycerol. -Capable of growth on 6% butanol	Nielsen et al. (2009) Rühl et al. (2009)

4.3.1.2. Simultaneous ABE fermentation and product recovery systems

Advanced fermentation technologies and downstream processing may be applied to overcome the low solvent tolerance of native or engineered ABE-producing microorganisms. A number of different *in-situ* recovery methods including adsorption, gas stripping, liquid-liquid extraction, perstraction, pervaporation, and reverse osmosis has been investigated for decreasing butanol microbial intolerance during ABE fermentation (Vane, 2005; Shao and Huang, 2007; Ezeji, 2010; Jiménez-Bonilla and Wang, 2018; Naidoo et al., 2018; Raganati et al., 2018; Azimi et al., 2019; Zhu et al., 2019). These real-time processes for removing butanol from the bioreactor during ABE fermentation have limitations that range from loss of nutrients to adsorbent, clogging, loss of fermentation (acetic and butyric acids) intermediates, and compatibility with utilization of only clean/pure substrates such as glucose and sucrose, thus, excluding the capacity for use of lignocellulosic biomass hydrolysates. Consequently, Ezeji's group at the Ohio State University, USA, have been developing a non-sparger, non-membrane-based vacuum-assisted gas stripping technology (VGST). Initial assessments indicated a 10-fold enhanced efficiency for real-time butanol recovery during fermentation compared to traditional gas stripping processes (Mariano et al., 2011; Mariano et al., 2012). With the VGST process, the fermentation is conducted at a reduced pressure in the bioreactor, causing butanol to boil off at the fermentation temperature (Mariano et al., 2012). It should be noted that the VGST process is compatible with the fermentation of impure fibrous or colloidal substrates as there are no problems with clogging or fouling. Even though there have been advances in these technologies, there is no known commercial application of any of these advanced fermentation technologies. In addition to the limitations highlighted in Table 9, the energy requirement for operating these advanced fermentation systems that enable simultaneous fermentation and *in situ* product recovery may be cost prohibitive, thus, impeding the commercialization of these processes.

4.4. Butanol derivatives as fuel additives: production, applications, and performance

Even though there is great potential of butanol as an automobile fuel, it has limited application as a high-performance military fuel. This is mainly because of the O₂ content of butanol, which limits its net heat of combustion as well as

relatively low flashpoint. To improve the fuel characteristics of butanol in this regard, a fully saturated fuel mixture can be produced through oligomerization of a derivative of butanol such as 1-butene, a linear alpha olefin, which can be generated with dehydration of butanol. Ethanol or methanol can also serve as a feedstock for the production of 1-butene by inducing C₂H₄ dimerization using Alphabutol process, which uses a metallacyclic mechanism involving titanium butoxide/triethylaluminum [Ti(OBu)₄/AlEt₃] or zirconium alkoxides with optimal selectivity of about 93% (McGuinness, 2011). Following distillation, 1-butene or its derivatives such as polyethylene or polypropylene can be used as fuel or as a fuel additive. Wright et al. (2008) produced a new jet fuel by subjecting 1-butene and oligomers to a hydrogenation process in the presence of platinum oxides (PtO₂) at 0.01 MPa. The final product was a fully saturated fuel mixture (C₁₂-C₁₆ oligomers) with a flash point, viscosity and lubricity values of 59 °C, 103 cSt, and 0.45 mm, respectively.

Similar to FAME, fatty acid butyl esters (FABE) are produced after reactions between vegetable oils containing fatty acid esters and butanol in the presence of a catalyst (Tabatabaei et al., 2019a). This biodiesel, which decreases the emission of HCs and NO_x as well as smoke production by diesel engines, can be blended with diesel without a change in performance. For example, combining esterified soybean and sunflower seed oils with butanol have resulted in a satisfactory performance and reduction in emissions when blended with diesel at 20% and used as fuel (Singh and Anbumani, 2011). Furthermore, biodiesel esters (*i.e.*, butyl and methyl) have been produced and characterized from *Azela africana*, *Cucurbita pepo*, and *Hura crepitans* seed oils (Ogbu and Ajiwe, 2016).

Two gasoline octane enhancement compounds, *i.e.*, *n*-butyl acetate and *n*-butyl acrylate have been respectively produced at industrial scales through esterification of *n*-butanol with AA in the presence of a suitable acid catalyst and the reaction of acrylic acid and *n*-butanol using strong acidic homogeneous catalysts. The treatment of butanol with H₂SO₄ or its catalytic dehydration in the presence of aluminosilicate (Al₂O₃Si), ferric chloride (FeCl₃), or copper sulfate (CuSO₄) at elevated temperatures is commonly used for the production of dibutyl ether (DBE), a diesel cetane oxygenate that improves self-ignition (Karas and Piel, 2005; Arteconi et al., 2011). Gómez Cuenca et al. (2011) reported that monoethylene glycol butyl ether (EGBE), a glycol ether, decreases cetane number and emissions (CO, HC, NO_x); whereas improves fuel lubricity and viscosity when

Fig. 5. Representative butanol-derivatives with fuel properties; DBE, dibutyl ether; EGBE, monoethylene glycol butyl ether; and FBE, fatty acid butyl esters.

applied as a diesel blend around 4 wt.%. The butanol-derived fuel additives are shown in Figure 5.

5. Ammonia

5.1. Background and possibilities

Although NH_3 is gaseous at temperatures higher than -33°C , it can easily be converted into a liquid state at a low pressure (about 0.1 MPa) without the use of special high-pressure tanks that are typically used for other gases such as CO_2 and H_2 ; thus justifying its consideration as a liquid fuel. Indeed, NH_3 is a high-density non-petroleum environmentally compatible liquid fuel (Table 10) which releases energy rapidly upon combustion. While the fuel mileage with use of NH_3 is half that of gasoline, it has no carbon emission when combusted. Interestingly, NH_3 is a potent H_2 storage carrier (17.6%), which could solve different drawbacks of using H_2 as fuel such as volatility and explosiveness. The idea of using NH_3 as a biofuel was developed in the 1980s (Strickland, 1981); however, investigations into using NH_3 to power car engines dates back to 1905 when Fiat Company (Italy) obtained the first patent on NH_3 fuel but subsequent vehicular applications by the Ammonia Cascade Company (Italy) were limited (Kroch, 1945; Stokes, 2007). In 1941 and 1942, NH_3 was successfully used to operate a fleet of 100 buses in Belgium during a time of shortage of traditional fuels due to World War II (Kroch, 1945; Stokes, 2007). There are also records for existence of NH_3 truck in 1933 (Holbrook, 2007), and more developed one that works on a mixture of NH_3 -gasoline with 4:1 ratio (Zamfirescu and Dincer, 2009). The availability of a distribution infrastructure, narrow range of flammability, rapid dissipation in air, and strong characteristic smell at even low concentrations for easy detection made NH_3 a unique alternative to conventional fuels at the time (Christensen et al., 2006; Thomas and Parks, 2006).

Interestingly, since the NH_3 molecule contains no C, its complete combustion results in the formation of only nitrogen gas (N_2) and H_2O vapor. Even though NH_3 (Table 10) has high octane rating (*i.e.*, 110-130), its flame speed is too slow to be directly used in ICE, thus necessitating engine modifications that feature compression ratios ranging from 40:1 to 100:1 (Van Blarigan, 2000; Feibelman and Stumpf, 2006), which are four times greater

than that for regular ICEs. The presence of H_2 in NH_3 can boost the combustion process (Brandhorst et al., 2008). Moreover, NH_3 can be thermally degraded into N_2 and H_2 by adsorption of approximately 12% of its higher heating value (HHV) (Jensen et al., 2007). The emission of NO_x can be nullified when fuel-air ratio (excess air over five) is adjusted (Wendt and Sterling, 1974). Another obstacle in application of NH_3 ; *i.e.*, toxicity has been previously addressed. For example, one method is passing NH_3 over an anhydrous magnesium chloride powder at ambient temperature to adsorb porous metal ammine complexes from NH_3 in the form of hexaamminemagnesium chloride [$\text{Mg}(\text{NH}_3)_6\text{Cl}_2$] (Zamfirescu and Dincer, 2009). A unique advantage of NH_3 for on-board application is its cooling property that allows downsizing of engine cooling system and providing some air conditioning. This ability can efficiently compensate for any energy consumed for cooling purposes in regular engine machines working through burning fossil fuels (Zamfirescu and Dincer, 2009).

Table 10.
Fuel properties of ammonia.

Chemical formula	NH_3
Structure	
Molar mass (g/mol)	17.03
Boiling point ($^\circ\text{C}$)	-33.34
Melting point ($^\circ\text{C}$)	-77.73
Density (kg/m^3)	0.73
Ignition temperature ($^\circ\text{C}$)	651
Flash point ($^\circ\text{C}$)	132
Thermal expansion coefficient (K^{-1})	2.4×10^{-3}
Calorific value (MJ/kg)	22.5
Air-fuel ratio (kg/kg)	6.06
Vapor pressure	7500 mmHg at 25°C
Heat of vaporization (MJ/kg)	1.37 at 25°C
Flammability limits (Vol.% in air)	15.5-27
Specific gravity at 20°C and 1atm	0.6819
Research octane No.	110 - 130

Overall, development of compatible technologies for production, distribution, and storage, may make global NH_3 -based vehicular applications attractive considering the zero carbon emission property upon combustion. Fuel properties of NH_3 in comparison with other fuels currently used in the transportation industry are presented in Table 11.

5.2. Chemical synthesis of ammonia

NH_3 is industrially produced using the Haber-Bosch process (costing ~ 495 USD/t NH_3) in which N_2 from air is reacted with CH_4 -derived H_2 in the presence of a Ru or Fe catalyst to generate NH_3 (Smil, 2001; Li et al., 2019). The process, however, is accomplished at high temperature and pressure; typically, at 475°C and 20 MPa, respectively. Additionally, for every metric ton of NH_3 produced, two metric tons of CO_2 are generated, and the recovery efficiency of NH_3 is about 38%, both of which have adverse economic and environmental implications.

5.3. Microbial production of ammonia

The production of NH_3 from non-fossil fuels can have an important effect on reduction of carbon and GHG footprints owing to the potential reduction in the amount of natural gas and other conventional fuels currently being used for its production. At least 24 bacterial genera, mostly isolated from the digestive tracts of ruminants and swine manure, have been used to produce different amounts of NH_3 . The hyper NH_3 -producing bacteria belong primarily to the genera *Clostridium*, *Eubacterium*,

Table 11.

Fusobacterium, *Peptostreptococcus*, and *Pseudomonas*, which when used have productivities as great as 681 mg/L/d (Whitehead and Cotta, 2004; Latvala et al., 2014).

The treatment of biological wastes such as agricultural residues, animal manures, animal blood from slaughterhouses, etc. utilizing anaerobic digestion processes is becoming attractive considering the human population growth and associated increased waste generation (Shirzad et al., 2019). For example, approximately 700 million tons/yr of animal manure are produced in the USA, with potential effects on air and water quality as well as ecological consequences such as eutrophication. Notably, NH₃ is one of the gases produced during anaerobic digestion. Approximately 1,700 (large scale), 17,400 (out of which 300 are large scale), 102,700, and 2,000,000 anaerobic digestion facilities are currently operational in USA, Europe, China, and India, respectively (Ho, 2005; Baere and Mattheeuws, 2010; USEPA, 2012; Scarlat et al., 2018; Shirzad et al., 2019). The NH₃ and ammonium ion (NH₄⁺), referred to as total ammonia nitrogen (TAN) which are interconvertible depending on pH and temperatures (Eqs. 2 and 3) (Rittmann and McCarty, 2012), are produced as a result of operation of these digesters. More specifically, the higher pH and temperature leads to the lesser proportion of N flux that is in form of NH₄⁺. Thus, pH and temperature conditions in the digester can be manipulated and exploited to produce and recover NH₃ from anaerobic digesters.

$$[\text{NH}_3 - \text{N}] = ([\text{TAN}]) / ((1 + ([\text{H}^+]) / K_a) \quad (\text{Eq. 3})$$

where, [NH₃-N] is the concentration of N in NH₃ and K_a is the temperature dependent dissociation coefficient.

To improve NH₃ production during anaerobic digestion, Babson et al. (2013) developed an approach in the process that shifts the production of CH₄ towards NH₃ synthesis. By adjusting the C:N ratio in the digestion feedstock, approximately 61% of total N flux was converted to NH₃ (Babson et al., 2013). Integration of a separate hydrolysis fermenter upstream of the anaerobic digester has been reported to prevent NH₃ toxicity to fermenting microorganisms and enhance digester stability (Babson et al., 2013). A novel process was patented in 2014 involving enzymatic hydrolysis of food industry wastes followed by microbial submerged fermentation (preferably *Clostridium* spp. deposited as VTT E- 123272 and VTT E- 123273) at optimized conditions (Latvala et al., 2014). At the end of fermentation process, TAN is recovered by using NH₃ gas capturing technologies while stripping is used to convert the ionic form (NH₄⁺) to NH₃ or alternatively, precipitation or mechanical methods may be used to recover NH₄⁺ (Latvala et al., 2014).

5.4. Ammonia recovery

Air or stream stripping is typically used for the recovery of NH₃ from NH₃-laden effluents from landfill leachate, municipal waste water treatment facilities, slaughterhouse waste digesters, dairy anaerobic digestion, and biogas plants (Jiang et al., 2010; Errico et al., 2018; Mavinic et al., 2019). Because NH₃ is easily dissociable in caustic solution, the stripping technique often involves a pretreatment step in which the pH of the effluent is increased using sodium hydroxide (NaOH) or limestone through multiple mixing operations in a stirred tank reactor. The resulting flocculated inorganic compounds such as carbonates, phosphates, and sulfates are either separated after conducting the

alkalization process in the sedimentation basins or retained throughout the entire process. The treated effluent stream is introduced at the top of the packed bed column from where it flows down to meet a counter-current air (lower operating costs) or steam (higher efficiency) flow that strips the NH₃ from the liquid phase. The NH₃ gas and treated H₂O are collected at the top and sump of the column, respectively. Further purification and treatment may include NH₃ distillation (NH₃-H₂O or anhydrous NH₃), absorption with an acid (salt solution) in a scrubber, and subsequent incineration. In the distillation step, NH₃ and H₂O vapors are passed through a condenser (low temperature) or a high-pressure column to form anhydrous NH₃. The cost of refrigeration makes the use of a condenser for the fractionation of NH₃-H₂O to pure NH₃ economically unattractive when compared to the pressurized column operating at about 1.4 MPa and temperature of 38 °C, which is amenable to use of cooling water for the fractionation of NH₃-H₂O vapors. From the biofuel industry perspective, stripping of NH₃ with steam is preferable as it allows the production of NH₃ with fewer contaminants. The ion exchange method of NH₃ recovery has not gained much attention due to the lack of capacity for utilization of large amounts of solids (<1%) with the use of this technology (Jiang et al., 2010).

5.5. Ammonia derivatives as fuel components: production, applications, and performance

In addition to being a potential transportation fuel, NH₃ can be used for production of fuel additives and feedstock chemicals that may be used in the production of fuels (Fig. 6). Oil soluble polyamines have been applied as dispersant additive to improve fuel detergency, which enhances the removal or prevention of deposits in the combustion chamber (Koeher and Claffey, 1999). Reaction of NH₃ with methanol in the presence of an Al₂O₃/Si catalyst leads to formation of three products, which includes monomethylamine (MMA), dimethylamine (DMA), and trimethylamine. These methylamines can be used as rocket fuels and fuel additives. Furthermore, a reaction between MMA and chlorobenzene (C₆H₅Cl) in the presence of Cu as a catalyst results in generation of *n*-methylaniline. Both *n*-methylaniline and dimethylamine hydrochloride (DMA-HCl) are important chemicals used in the production of "antiknock" aviation fuel additive. There have been suggestions that DMA could be a potential gasoline additive with a 10% (v/v) DMA incorporation to gasoline to increase the octane number of gasoline by five (Ezeldin et al., 2015). With the reaction between DMA salt and sodium nitrate (NaNO₃), there is generation of dimethylnitrosamine (DMNA) which can be oxidized with chloramine (NH₂Cl) to produce 1,1-dimethylhydrazine (UDMH), a propellant for rockets. Dimethylaminopropylamine (DMAPA) is produced by reacting DMA with acrylonitrile (C₃H₃N) in a process referred to as Michael reaction followed by a hydrogenation step. The generated compound which contains one primary and a tertiary amine group serves as an intermediate feedstock for the production of various fuel additives (Huntsman, 2017). For example, when DMAPA is reacted with polyisobutylene chloride, a fuel additive is produced which is capable of preventing engine fouling and reducing HC exhaust gas emissions. A reaction between α, β-dibromopropionitrile and DMAPA can be utilized for generation of an effective carburetor cleaner. Other carburetor detergents have also been produced by reacting DMAPA with alkylphenols and aldehydes or with thioglycolic acid and chlorinated polyisobutene (Huntsman, 2017). Furthermore, ash-free lubricant additives have been

produced by using a reaction between DMAPA and C_2H_4 , C_3H_6 , or 1,4 hexadiene copolymer. Indeed, [Huntsman \(2017\)](#) formulated a lubricating oil additive with improved anti-corrosion, dispersancy, and anti-wear properties by reacting DMAPA with alkyl phenol, formaldehyde, and sulfur.

In addition to methanol, NH_3 can be reacted with ethanol to produce fuel additives. For example, the reaction of NH_3 and ethanol results in generation of diethanolamine (DEA), an industrial amine that confers lubricity and anti-wear properties to fuels. While some of these reactions do not generally result in production yields that justify commercialization, there can be platforms developed utilizing this knowledge for further research to bring to fruition the development of NH_3 as a non-carbon fuel.

Fig. 6. Fuels and fuel additives from ammonia; DEA, diethanolamine; DMA, dimethylamine; DMA-HCl, dimethylamine hydrochloride; DMAPA, dimethylaminopropylamine; DMNA, dimethylnitrosamine; and UDMH, 1,1-dimethylhydrazine.

6. Bio-jet fuels (biokerosene)

6.1. Background and possibilities

The aviation industry is an essential part of modern mobility of people, goods, and services. Aviation transportation is responsible for the release of 2.4% of the 13.5% global CO_2 released by the transport sector. In 2018, up to 346 million m^3 (~2.72 billion barrels) of jet-fuel was consumed which is expected to reach 441 million m^3 (~3.47 billion barrel) in 2040. The rapid growth in jet-fuel consumption in 2018 conveniently exceeded by 4% (typical expectations of 1-3%) compared with value recorded in the preceding years ([Babau et al., 2013](#); [Holbrook, 2018](#)). Commercial airplanes are generally operated with jet kerosene, a relatively safe energy dense fuel with desirable combustion quality. A summary of the fuel properties of kerosene are included in [Table 12](#). Kerosene is an oil distillate, which can also be extracted from oil shale, coal, and wood. The methods of kerosene production from petroleum will not be included in this review. There, however, will be inclusion of information about biosynthesis processes involving microbial conversion of organic matter into kerosene or its intermediate compounds.

Table 12.

Fuel properties of kerosene.

Chemical formula	Mixture of hydrocarbons (C9 to C16)
Molar mass (g/mol)	170.34
Boiling Point ($^{\circ}C$)	15-300
Melting point ($^{\circ}C$)	-20
Density (kg/m^3)	800
Ignition temperature ($^{\circ}C$)	220
Flash point ($^{\circ}C$)	37-65
Thermal expansion coefficient (K^{-1})	9.6×10^{-4}
Viscosity (m^2/s)	2.39×10^{-4}
Calorific value (MJ/kg)	35
Air-fuel ratio (kg/kg)	15.6
Vapor pressure	0.7 kPa
Heat of vaporization (MJ/kg)	43.1
Octane No.	15-20

6.2. Microbial production of bio-jet fuel

The Amyris direct sugar to hydrocarbon (DSHC) process is probably the most desirable method for the production of bio-jet fuel as the process can be utilized for generation of aviation kerosene that meets the American Society for Testing and Materials (ASTM) D7566 specifications ([Neuling and Kaltschmitt, 2015](#)). The use of the process results in conversion of sugars from corn, sugarcane, and lignocellulosic biomass to C_{15} alkenes that are termed Farnesenes ($C_{15}H_{24}$), and other by-products through utilization of the mevalonate pathway with genetically engineered yeast and enzymes as biocatalysts in an advanced aerobic fermenter. The production of the enzymes and the cultivation of the yeast are performed in separate vessels ([Saha et al., 2005](#)). The generated $C_{15}H_{24}$ is extracted and saturated to form Farnesane ($C_{15}H_{32}$) by using hydrotreating processes. This process can be used to generate valuable compounds for the chemical and pharmaceutical industries ([Saha et al., 2005](#)). In 2015 the Amyris DSHC process is operated on a small-scale, generating approximately 24,000 tons $C_{15}H_{32}$ per annum in Brotas, Brazil ([Neuling and Kaltschmitt, 2015](#)).

Alcohol-to-jet fuel (AtJ) is another method through which organic materials can be converted into jet fuel using fermenting microorganisms and enzymes as biocatalysts. In this process, alcoholic feedstocks such as ethanol and butanol which have been previously produced through microbial fermentation of sugar, starch, or lignocellulose-containing raw materials, are dehydrated using acid (H_3PO_4 or H_2SO_4) catalytic reactions at 170 to 200 $^{\circ}C$ in the presence of metal oxide catalysts to form alkenes ([Breitmaier and Jung, 2005](#); [Wollrab, 2009](#); [Pechstein et al., 2018](#)). Catalytically controlled oligomerization of generated short-chain alkenes (C_4H_{10} or C_2H_6) to longer molecules is subsequently performed ([Neuling and Kaltschmitt, 2015](#)). The generated product is separated and treated with H_2 to saturate alkenes to alkanes in the presence of a catalyst such as Ni, palladium (Pd), or Pt. A fuel cocktail comprising 48% kerosene, 35% gasoline, and 17% diesel is obtained ([Hull, 2012](#)). Although the reaction can be performed at ambient pressure and temperature, the performance can be improved at greater pressures and/or temperatures ([Breitmaier and Jung, 2005](#)). Byogy Renewables Inc. is the leading company that has adapted the AtJ process for the production of kerosene using ethanol and H_2 as feedstocks ([Weiss, 2013](#)). Similarly, LanzaTech/Swedish Biofuels produce ethanol from gasified biomass or industrial waste gases utilizing synthesis gas fermentation processes followed by the use of AtJ method for conversion of ethanol and C_4H_8 to kerosene ([Holmgren, 2013](#)). Gevo uses the AtJ process to produce synthetic paraffinic kerosene from isobutanol derived from fermentation of hydrolyzed lignocellulosic biomass ([Johnston, 2013](#)). For examples, Gevo operates a small demonstration plant with a total production capacity of about 290 tons/yr in Silsbee, Texas, and Swedish Biofuels operates a working pilot plant producing 10 metric tons/yr bio-jet fuel in Stockholm, Sweden ([Hull, 2012](#); [Johnston, 2013](#)).

Table 13.

Comparison of various microbial techniques for bio-kerosene production with commercial HEFA processing. Source: Neuling and Kaltschmitt (2015).

Process	Feedstock	Additive	Process complexity ^a	Kerosene efficiency	Overall efficiency	Production cost ^b	Market maturity	Developmental potential
HEFA	All types of oils and fats	Large amount of H ₂ ; NiMo/ Al ₂ O ₃ , zeolites (ZSM) or Pt metal catalysts	-	<50%	<60%	-	Commercially operated	Low
Amyris DSHC	Biomass ^b	Low amount of H ₂	Higher	About 97%	<97%	Higher	Demo-plant	High
AtJ	Biomass	Low amount of H ₂ ; Ni, Pt, Pd catalysts	Similar	48%	NA	Higher	R&D process	High
Bio-GtL	Biomass except lignin	Large amount of H ₂ , O ₂ , and solvents for CO ₂ separation; Co or Ru catalysts	Similar	50-60%	NA	Similar/ Higher	R&D process	Medium

HEFA, hydroprocessed esters and fatty acids; NA, not applicable; DSHC, direct sugar to hydrocarbon; AtJ, alcohol-to-jet; R&D, research and development; GtL, gas-to-liquid

^a Compared to HEFA^b Starch, sugar and lignocellulosic biomass

Intriguingly, Gevo's AtJ was utilized as a 20% blend in a test commercial flight by Alaska Airlines and the fuel met the international ASTM standards (Alaska Airlines, 2016; Gevo Inc, 2016).

Gas-to-liquid (GtL) processes as a potential cost effective microbial process for the production of kerosene has also been investigated. With this method, CH₄ derived from anaerobic digestion of various organic wastes (such as corn silage, grass silage, and sugar beets) can be transformed into bio-kerosene via syngas to gasoline plus (STG+) process with a thermochemical single-loop or FT process (LaMonica, 2012; Shirzad et al., 2019; Tabatabaei et al., 2019b). GtL process for kerosene production is attractive because the anaerobic digestion technology for the production of the chief feedstock (CH₄) is mature and economically viable (if all benefits of anaerobic digestion process are considered) (Neuling and Kaltschmitt, 2015; Shirzad et al., 2019). The process is initiated with the breakdown of CH₄ to CO and H₂ using steam CH₄ reforming, POX, or autothermal reforming (ATR), which results in the generation of a H₂:CO mixture (i.e., syngas) (De Klerk, 2012). In the STG+ process, the syngas is transferred sequentially through two reactors with compatible catalysts to generate methanol, which is dehydrated to form DME (see Section 2.4). In the third reactor, the DME is catalytically transformed into HCs including kerosene, aromatics, naphthenes, and trace amounts of olefins. The fourth and last reactor is where transalkylation and hydrogenation steps occur resulting in the reduction of durenene and trimethylbenzene contents of the HCs to improve the octane rating and desirable viscometric properties of the generated fuel. Following separation of gas and liquid products, residual gases are recycled to the feed stream of the first reactor whereas the liquid fuel that is composed of kerosene, aromatics and naphthenes is transferred to a storage tank <http://www.primusge.com/press-room/white-papers/>.

In the FT process, the H₂:CO ratio is adjusted using the H₂O-gas shift process while the excess CO₂ is removed either with compatible solvents or dissolved in aqueous solutions of alkanolamines. The syngas is then converted into long-chain HCs in a reaction that uses Co, Fe, or Ru catalyst. Table 13 presents comparison between processes used for the production of bio-kerosene with the commercial hydro-processed esters and fatty acids (HEFA) process (Neuling and Kaltschmitt, 2015). The HEFA process involves hydrogenation of triglycerides followed by isomerization to branched alkanes to meet the ASTM D7566 specifications, and separation using distillation procedures. These reaction processes are conducted at an elevated pressure (10 MPa) and a high temperature (400 °C). Notably, the use of the HEFA process allows for algal and microbial triglycerides to be used as feedstocks for kerosene production (Robota et al., 2013; Yeh et al., 2013), an important development decreasing the reliance on food-grade vegetable oils such as palm, rape, peanut and soybean oils as feedstock.

7. Glycerol

7.1. Background and possibilities

Glycero can be produced naturally by some microorganisms, e.g., *S.*

cerevisiae or by chemical synthesis in the petrochemical and soap industries. Glycerol is also a major co-product of the biodiesel industry, where animal fats and vegetable oils (both containing long chain fatty acids) are converted into biodiesel by reaction of these feedstocks with short-chain alcohols such as ethanol or methanol (Tabatabaei et al., 2019a). The reaction process, termed the transesterification reaction, can be accelerated by addition of heat and catalysts such as KOH, sodium methoxide (CH₃ONa), and NaOH. The transesterification of triglycerides results in the formation of mono-alkyl ester (biodiesel) and approximately 10% to 15% crude glycerol (co-product) (Quispe et al., 2013; Tabatabaei et al., 2019a).

Microbial production of glycerol for use as a biofuel is not technically and economically feasible (Wang et al., 2001; Quispe et al., 2013). More specifically, when glycerol is combusted, there cannot be maintained a stable flame in a conventional combustion system due to its low calorific value and/or presence of H₂O in the mixture. Glycerol is viscous at ambient temperatures, thus, rendering atomization with conventional atomizers problematic (Tabatabaei et al., 2019a). Crude glycerol, especially as a co-product of the biodiesel industry, contains salts, which are corrosive in combustion injectors and in post combustion systems. Alternatively, glycerol can be combusted in specially-designed boilers for the generation of heat and electricity (Quispe et al., 2013). The production of combustible pellets by mixing waste glycerin with waste biomass for substitution of coal for energy generation is another option (Brady et al., 2008). Some properties of glycerol are described in Table 14. The application of glycerin as a fuel additive has been studied by Mota et al. (2010). When there was blending of solketal (glycerin reacted with ketal) with gasoline in amounts as much as 5% (v/v), the octane number of the gasoline-glycerol blend was increased by 2.5 points, and there was decreased gum formation. Additionally, the potential blending of gasoline with derivatives of glycerol such as propanediol and propanol as oxygenates has been suggested (Fernando et al., 2007). These derivatives and other valuable products such as citric acid, dihydroxyacetone, ethanol, LA, pigments, polyhydroxyalcanoate, propionic acid (PA), and SA can be synthesized through utilization of a compatible microorganism.

7.2. Microbial production of glycerol

Glycerol production using chemical synthetic procedures is no longer an attractive process mainly due to impractical economic cost of the major precursor for this process, i.e., C₃H₆, on one hand and the improvements made in microbial fermentation and glycerol recovery techniques on the other hand (Hester, 2000). The technology shift for glycerol production has also occurred because of the marked replacement of conventional animal-fat-based-soap with detergents. Currently, glycerol is still applied as humectant in some types of soap or other cosmetic products available in the market. The fermentation process can occur with use of various microorganisms such as bacteria (*B. subtilis*, *Bacillus welchii* and

Table 14.
Fuel properties of glycerol.

Chemical formula	C ₃ H ₈ O ₃
Structure

Lactobacillus lycopersici), yeasts (*Candida boidinii*, *Candida magnolia* I₂B_a, *Candida glycerinogenes*, *Pichia farinose*, *S. cerevisiae*, *Saccharomyces ellipsoideus*, and *Z. rouxii*), molds, and algae. While glycerol production using bacteria has been unattractive due to the slow fermentation rate and low yields of product (Wang et al., 2001), glycerol production with yeast, *S. cerevisiae*, has been relatively attractive and successful with the process currently being utilized commercially. Glycerol metabolism in *S. cerevisiae* occurs in the cytosol, and involves the glycolytic intermediate dihydroxyacetone phosphate (DHAP) through the catalytic activity of glycerol-3-phosphate dehydrogenase and glycerol-3-phosphatase (Wang et al., 2001). In anaerobic fermentation process using this yeast to produce glycerol, ethanol production should be retarded by trapping acetaldehyde in a complex through the addition of bisulfite ions (the steering agent). Under this condition, electron transfer from the cytosolic NADH to acetaldehyde cannot occur and instead, the accumulated NADH is oxidized through the reduction of DHAP to glycerol-3-phosphate. Alternatively, the fermentation can also be conducted as normal alcoholic fermentation at neutral or alkaline pH (7 ≤). In this process, NADH molecules are generated as the result of acetaldehyde oxidation to AA. When there is no O₂ available, the re-oxidation of this NADH molecule takes place through DHAP reduction to glycerol-3-phosphate which is further converted into glycerol. Sparging of the bioreactor with CO₂ or strict application of aeration control has been found to increase the efficiency of glycerol production to as great as 40% (Wang et al., 2001).

The relatively low glycerol titer in fermentation broth and its high cost of recovery are the main challenges for commercial bio-glycerol producers (Wang et al., 2001). These limitations can be mitigated by the development of osmotolerant yeasts without loss in glycerol producing capacity. Use of these yeast strains can result in fermentation of as much as 45% (w/w) of the total sugar with an improved glycerol production in an aerobic fermentation process with no requirement for steering or osmotic solutes. This process is simpler with reduced contamination risk when compared to conventional methods where bisulfites or alkali techniques are used for glycerol production. Commercial production of glycerol has been reported in a 50,000-L airlift fermenter with an average yield of 51 wt.% using genetically-modified *C. glycerinogenes* (Zhuge et al., 2001).

Additionally, glycerol is produced as a co-product during ethanolic fermentation. The most feasible approach for the recovery of glycerol (about 90%) from fermentation broth is by the use of a patented technique known as carrier-distillation in which cell debris and dissolved solids are initially removed by filtration followed by the addition of inorganic inert materials to the filtrate and distillation at 160 to 180 °C (Zhuge and Liu, 1990). This technique can be coupled to an ion-exchange chromatography for the production of medical grade glycerol. Other methods including a vacuum

distillation technique have also been tested. While use of the ion exclusion method in conjunction with ion exchange has been reported to result in production of glycerol of high purity, the extensive pretreatment of the fermentation broth prior to glycerol recovery makes the process cost prohibitive (Zhuge et al., 2001).

In a cost-benefit analysis performed in the year 2000, the cost of microbial glycerol production was estimated to be between US\$ 400/t and US\$ 530/t, vs. its price of US\$ 1100/t to US\$ 1250/t in the same year indicating its profitability (Hester, 2000). However, this scenario drastically changed through the increasing establishment of the biodiesel industry resulting in surplus availability of as glycerol (the main co-product of the transesterification reaction) and consequent fall of glycerol market price.

7.3. Glycerol derivatives as fuel additives: production, applications, and performance

Conversion of glycerol to value-added products such as fuel additives (Fig. 7) has received remarkable attention in the past decade due to the surplus of glycerol that resulted from the increased production of biodiesel worldwide (Rahimzadeh et al., 2018; Tabatabaei et al., 2019a).

Fig. 7. Reported glycerol derivatives with fuel enhancing properties; 2BGMH, 2-butanone-glycerol and methyl hexanoate; BGE, butyl glycerol ethers; DBG, di-butoxy glycerol; EEG, ethyl ether of glycerol; FAGE, fatty acid formal glycerol ester; GDME, glycerol dimethoxy ether; GTBE, glycerol *tert*-butyl ethers; GTME, glycerol trimethoxy ether; PGE, propyl glycerol ethers; and STBE, solketal *tert*-butyl ether.

The addition of ketal derivatives of glycerol into biodiesel improves cold flow properties and maintains iodine and viscosity values of the fuel blend. However, the free hydroxyl group of glycerol must be esterified prior to its addition into biodiesel to meet the EN14214 specifications with respect to the FAME content and oxidation stability (De Torres et al., 2012). Glycerol ketal esters, a transesterified product of 2-butanone-glycerol and methyl hexanoate (2BGMH), has been proposed for use as a promising diesel fuel additive for the reduction of smoke emission in diesel engines (Oprescu et al., 2014; Tabatabaei et al., 2019a). Fatty acid formal glycerol ester (FAGE), produced from glycerol and used cooking oil or waste animal fats subjected to a transketalization–transesterification combined process, has been reported to improve the lubricity of the diesel fuel (Lapuerta et al., 2015). Glycerol can also be bio-converted to FAGE using an engineered *E. coli* strain YL15 with highly acceptable production efficiencies (813 mg/L)

(Yang et al., 2013). The combustion of diesel containing 20% FAGE, however, resulted in increased NO_x, CO, and PM emissions at cold engine temperatures due to the high viscosity and poor volatility. The inclusion of solketal resulted in a reduction in gum formation and improvement in fuel octane point-number by 2.5. Shirani et al. (2014) produced solketal in a continuous reactor by ketalization of glycerol with use of subcritical acetone and Purolite® PD206 as a catalyst at 20 °C and a pressure of 12 MPa with a 95% product yield. Solketal can be converted into a novel biodiesel oxygenate additive such as solketal tert-butyl ether (STBE) using either batch or continuous flow processing (Vicente et al., 2010; Monbaliu et al., 2011; Tabatabaei et al., 2019a). While there has been some progress, the batch etherification of solketal with C₄H₈ remains to be a challenging approach due to the significant safety measures needed during industrial scale production as well as reagent immiscibility in the early reaction stage.

Furthermore, Spooner-Wyman et al. (2003) evaluated the production of dibutoxy glycerol (DBG) by etherification with isobutylene for use as a diesel fuel blend. The results of the study indicate that DBG is a promising diesel fuel additive with the capacity to reduce PM emissions during diesel combustion. Similarly, Nouredini et al. (1998) was able to induce catalytic etherification of glycerol with isobutylene at 80 °C for 1 to 2 h and the corresponding glycerol ethers formed were compatible for use with diesel and biodiesel fuels. There was a reduction in the cloud point and viscosity of biodiesel by 5 °C and 8%, respectively, when the glycerol ethers were blended at 20% in diesel and biodiesel fuels (Nouredini et al., 1998). Alternatively, Saengaran et al. (2017) reported on the etherification of glycerol with 1-butene or C₃H₆ with addition of an acidic heterogeneous catalyst (that included amberlyst-15, S100, and S200 resins) for synthesis of butyl glycerol ethers (BGEs) or propyl glycerol ethers (PGEs), respectively. When blended with palm oil derived diesel, BGEs and PGEs can be used to reduce the cloud point, thus, improving flow capacity of diesel fuel and increasing the life spans of fuel filters and injectors in engines.

8. Conclusions

Different types of liquid biofuels (*i.e.*, bioethanol, biomethanol, biobutanol, bio-ammonia, biokerosene, and bioglycerol) that could be produced by microbial processes including their advantages and disadvantages from fuel properties perspective have been comprehensively reviewed in this article. In order to understand the mechanisms behind each biochemical process, the fuel-generating microorganisms, different biological pathways, some main influential parameters on microbial biofuel production, as well as deficiencies and limitations of microbial-based processes have also been scrutinized.

Currently, ethanol (143 billion liters produced in 2017) is the world largest biofuel consumed, 80% of which is produced by fermentation. The application of bioethanol as fuel extender is popular and many countries support blending gasoline with ethanol up to 10%, v/v. On the dark side, the world top two bioethanol producing countries, *i.e.*, the USA and Brazil, accounting for more than 85% of the total amount of bioethanol produced globally from 2007 to 2015 utilize corn and sugarcane, respectively. The application of these food commodities could nullify the advantages of using bioethanol and in some cases, could even have negative consequences. To address this concern, lignocellulosic feedstocks should be more seriously exploited. In fact, there is mature knowledge and technology for lignocellulose-based bioethanol production but some economic constraints on the way of its global commercialization must first be resolved.

Butanol is the best liquid microbial biofuel for substituting gasoline and diesel with respect to fuel characteristics, *i.e.*, energy content, hydrophobicity, flash point, low volatility, miscibility, and octane-enhancement property, greater heat of evaporation, and reduced NO_x emissions. However, compared to bioethanol, 8-18 times lower concentrations of biobutanol could be reached during fermentation limiting its application as biofuel. The commercialization of biobutanol has been significantly improved by metabolic engineering techniques. Sustainable biobutanol production from non-food substrates, increasing tolerance to biobutanol titer in biobutanol-producing microorganisms, and enhancing biobutanol recovery from fermentation broth, are among the major challenges to overcome to pave the way for economically viable commercialization of this green fuel.

Methanol is also a good fuel extender, and it can be produced from CH₄ conversion by some microorganisms. Therefore, anaerobic digestion process may be coupled with the methanol industry to convert the raw biogas generated into methanol, which is a better transportation fuel than CH₄. For a successful

biomethanol production, the microorganisms involved should be engineered by manipulating their MDH enzyme while electron donors such as formate should also be provided to enhance methanol accumulation in bioreactors and prevent the oxidation of produced methanol to CO₂ by methanotrophs. However, despite some achievements, the current commercial microbial production of methanol is not yet profitable.

Microorganisms could also contribute to bio-jet fuel production from various feedstocks (sugar, starch, and lignocellulose) *via* different technologies such as DSHC, AtJ, and Bio-GtL. Among these processes, DSHC has already reached the demo-plant stage and has the most complex process with high overall efficiency of up to 97%. Intriguingly, despite lower additives requirement such as H₂ by DSHC and AtJ processes, Bio-GtL could be conducted at relatively lower costs. The kerosene yield of DSHC, AtJ, Bio-GtL techniques stands at ~97%, 48%, and 50-60% the last two techniques are still in at R&D stage though.

The production of NH₃ through microbial processes is also well-known; however, its application as biofuel still requires further development of specifically designed ICEs. The other impediment on the way of NH₃ application as biofuel is the concern that owing to the main application of NH₃ as biofertilizer (source of nitrogen), such an approach could result in adverse consequences to the agricultural sector. In contrast to ammonia, the interest for microbial production of glycerol has declined since 2001 due to the rapidly growing biodiesel industry, delivering ample amounts of glycerol as co-product. Moreover, it is not possible to burn glycerol directly in ICEs but recently, efforts are directed toward its conversion into some promising fuel additives.

It should also be highlighted that desired characteristics for production of biofuels and precursors of interest could be effectively conferred to appropriate microorganisms *via* rapid, rational, and extremely powerful metabolic engineering techniques, *i.e.*, by introducing entire new pathways or modifying existing ones. This allows the development of superior microbial cell factories, required for commercialization of biofuels. For instance, modified microorganisms could assimilate new substrates, which could not be previously degraded by them, subsequently increasing the economic profitability of the microbial biofuel production systems. In addition to technological developments to improve microbial biofuels production, development of coherent social and environmentally compatible strategies and framework policies that result in reductions in fossil fuel subsidies in favor of biofuels could play a substantial role in increasing investments in these green energy carriers.

Overall, it could be concluded that microbial biofuels production under the biorefinery scheme employing waste-to-biofuel technologies as well as the subsequent conversion of the generated biofuels into various fuel additives as value-added products could be a promising solution to boost the global economy and mitigate climate change simultaneously.
